Whereas breast-feeding is associated with mother to child transmission of HIV infection and is not recommended in urban areas with access to formula preparations, it remains the preferred mode of feeding in resource-poor areas where formula use is not possible. WHO now encourages breast-feeding exclusively in women when adequate and safe formula feeding is not possible.92

The preferred means of diagnosis of perinatal HIV infection is by the use of assays to detect viral RNA or DNA. Two negative viral assays, with at least one after 4 months of age, means that the infant can be labeled seronegative. In addition, two negative tests after 6 months of age, with the absence of other clinical symptoms or suggestive laboratory findings, can be used to rule out infant disease. Infants with AIDS typically present with recurrent bacterial infections, Pneumocystis pneumonia, encephalopathy, extrapulmonary tuberculosis, and generalized wasting. The effects of pregnancy in women with symptomatic HIV infection include an increased incidence of infant mortality, prematurity, stillbirth, and low birth weight, delivery by cesarean section, and gestational diabetes.103-105 Seropositive mothers who undergo cesarean delivery generally have an uncomplicated postoperative course, although some studies have noted a slightly increased risk of postpartum endometritis and other maternal infections, with the highest rate of infection seen in women who have low CD4+ cell counts.106 It is also important to consider the effect of HAART on pregnancy outcomes. Overall, however, most antiretroviral medications are considered safe in this regard. Several large studies have noted no increase in adverse outcomes in women taking HAART,107 with the possible exception of preterm delivery, although this remains controversial.108,109 In the absence of retroviral therapy, HIV disease progression during pregnancy is moderate, and the risk of HIV negative outcomes increases. When HAART is used in pregnancy, there appears to be no increased risk of disease progression.110

Tuberculosis

It is estimated that tuberculosis (TB) complicates in excess of 200,000 pregnancies worldwide annually.111 Most of these occur in Africa. The acquisition and presentation of TB are unchanged during pregnancy, but the effect of TB on pregnancy is unclear. Preconception, active genital TB disease increases the risk of an ectopic pregnancy.112 Accurate assessment of the risk of maternal and neonatal morbidity has been difficult to ascertain,113 but there seems to be consensus that complications are more likely in patients with inadequate or delayed diagnosis and treatment and in those with extrapulmonary (extranodal) tuberculosis. Delayed diagnosis is common in pregnancy because TB symptoms are atypical during gestation.114,115 This is an even greater challenge in those patients co-infected with HIV who will likely fail WHO screening guidelines on surveillance for pulmonary TB (16% vs. >90% compared to nonpregnant women).116 Neonatal tuberculosis acquired by exposure to undiagnosed and untreated active disease places infants at significant risk for acquiring tuberculosis during the first year of life, with significant mortality. In addition, congenital tuberculosis is possible after the fetus becomes infected through the placenta or via aspiration of infected amniotic fluid. The latter is rare if the mother has received appropriate therapy. Definitive treatment is indicated in all pregnant patients with confirmed tuberculosis as well as in those high-risk women with suspected disease (see Table 179.3). Moderate to severe anemia, particularly in HIV-positive mothers, has a strong association with undiagnosed TB and should prompt screening.117 Isoniazid, ethambutol, and rifampin in their usual doses have not shown to be teratogenic to human fetuses and are acceptable during pregnancy and breast-feeding. Standardized, second-line treatment for multidrug resistant TB appears to be safe in pregnancy.118

Syphilis

The incidence of primary and secondary syphilis among US reproductive age women has steadily increased since the late 1990s, when there were hopes of eradicating the disease. Significant differences in ethnic distribution of the disease have been noted, with current rates of 4.5/100,000 in African Americans, 2.5/100,000 in Hispanics, and 1.0/100,000 in whites.119 Unfortunately, the incidence of congenital syphilis has shown a similar increase from 2005 to 2008, with a current rate of 8.2/100,000 live births.120
Syphilis causes numerous gestational complications (see Table 179.3), but its most significant sequela is congenital syphilis. This syndrome is characterized by hepatosplenomegaly, osteochondritis, jaundice, rash, lymphadenopathy, rhinitis, Hutchinson’s teeth, and anemia. Infant mortality for cases within the last decade was 6.5%. Fetal ultrasonography before the 20th week of gestation is indicated to assess for abnormalities consistent with congenital syphilis. Sonographic signs of fetal syphilis confer a higher risk of congenital syphilis at delivery, and few of these completely regress after sufficient treatment. Treatment is identical to that given to nonpregnant patients, with the use of benzathine penicillin G appropriate for the disease stage (see Table 179.3). Perinatal transmission is approximately 10% to 20% in women seropositive for HBV surface antigen (HBsAg) alone but approaches 90% in mothers who are seropositive for HBsAg and HBV envelope antigen (HBeAg); it is also more likely if the mother has acute infection during the third trimester. Of infants who have HBV infection, up to 90% become chronic carriers as adults and are at risk for complications such as cirrhosis and hepatocellular carcinoma.

Studies have suggested that lamivudine given in late pregnancy to women with high viral loads of HBV DNA reduces viral transmission when given in conjunction with HBV vaccine and immune globulin. Infants of HBsAg-positive mothers should receive hepatitis B immune globulin and the first dose of vaccine within 12 hours of birth. Two additional doses of vaccine are administered at a later date.

Hepatitis C

The worldwide prevalence of hepatitis C virus (HCV) infection in pregnant women is estimated to be between 1% and 8%. As with HBV, the prevalence of hepatitis C virus (HCV) infection among pregnant women varies by geographic location and ethnic subculture within a population, ranging from less than 1% to approximately 4%, with white mothers having higher infection rates than black or Hispanic mothers. Vertical transmission is rare in mothers with anti-HCV antibodies and no circulating HCV RNA. However, perinatal transmission is significantly increased by the presence of HCV viremia, occurring in approximately 4% to 6% of cases. The transmission rate is even higher in the setting of co-infection with HIV; the rates of HCV co-infection with HIV are about 10-fold higher than that seen in non–HIV-infected mothers. Perinatal transmission is now the leading cause of HCV transmission to children in developed countries. Cesarean delivery has not been shown to prevent HCV transmission. There is no available vaccine or immune globulin to prevent hepatitis C, and routine prenatal screening is not indicated.

INFLAMMATORY DISORDERS

Rheumatic diseases or collagen vascular diseases are characterized by sterile inflammation in multiple anatomic sites. The most common rheumatic diseases encountered in pregnancy are systemic lupus erythematosus (SLE) and rheumatoid arthritis (RA). Gravid patients with collagen vascular disease may have preexisting cardiovascular or renal compromise and may not tolerate the increased intravascular volume and other physiologic changes that occur during pregnancy.

Systemic Lupus Erythematosus

SLE primarily affects women of reproductive age, but fertility is usually unaffected. The disease course during pregnancy varies, but studies have indicated that acute flares occur in less than one-third of patients in clinical remission at the time of conception. Disease activity tends to involve the skin and musculoskeletal system, although renal involvement is not uncommon, especially in patients with active lupus nephritis. The gestational effects of SLE also depend on the underlying severity of disease. Patients with active disease at pregnancy onset with symptoms of hypertension, thrombocytopenia and, especially those with preexisting lupus nephritis, have a higher incidence of disease flares and pregnancy complications. Many patients have acceptable outcomes, but lupus pregnancies are associated with an increased maternal mortality and increased rate of other complications, including preterm delivery, thrombocytopenia, anemia, intrauterine growth retardation, fetal loss, and need for cesarean section.

The risk of preeclampsia is increased up to 14% in lupus-related pregnancies; initiation of low-dose aspirin therapy prior to 16 weeks’ gestation decreases the risk of preeclampsia. The development of preeclampsia in women with a history of SLE seems to have a predictive association with subclinical coronary vascular disease. This should prompt consideration of less exertional delivery methods as well as drive postpartum medical decision making to evaluate for coronary artery disease.

Other comorbid conditions that adversely affect pregnancy, such as diabetes and thrombophilia, are also seen more commonly in SLE patients. The risk of preeclampsia is especially increased in those with active lupus nephritis. As with other renal disease, increasing proteinuria warrants a careful evaluation to distinguish between lupus glomerulonephritis and preeclampsia. The presence of abnormal urine sediment, increasing titers of anti-DNA antibody, and decreasing levels of C3 and C4 suggest lupus nephritis.

Neurologic disease in SLE may be manifested as psychosis, seizures, chorea, or peripheral neuropathy. The incidence of these complications is low during pregnancy, although the occurrence of seizures in late pregnancy in patients with coexistent hypertension and renal insufficiency may pose a diagnostic dilemma between the neurologic effects of SLE and signs of eclampsia. Elevated levels of lupus anticoagulant and antiphospholipid antibodies have emerged as markers of disease activity and are good predictors for adverse pregnancy outcomes.

Rheumatoid Arthritis

RA is characterized by chronic, destructive, symmetric joint inflammation. Less common manifestations include the development of subcutaneous nodules, neuropathy, pleuroperticarditis, and vasculitis. Systemic symptoms, including weight loss,
lymphadenopathy, and fatigue, are common. Because the median age at onset is later with RA, this disorder is seen less frequently than SLE in the pregnant population. Immune tolerance mechanisms are upregulated in pregnancy to decrease fetal rejection. In rheumatic diseases, this typically results in disease improvement, which has been estimated to occur in approximately two-thirds of patients with RA.

Patients with RA tend to have good pregnancy outcomes in the setting of well-controlled disease. Women with active disease are more likely to have small-for-gestational-age infants, possibly as a result of underlying vasculopathy and associated effects on the placenta.

Treatment

Corticosteroids are the mainstay of therapy for most rheumatologic complications or exacerbations. Aspirin has been advocated for all lupus-related pregnancies of more than 16 weeks’ gestational age, and other NSAID regimens remain useful treatments for inflammatory flares. A full discussion on fetal teratogenicity and fetal complications of these agents can be found in Chapter 180.

Second-line therapy for rheumatic diseases can include cytotoxic agents such as cyclophosphamide and methotrexate. These are both potent teratogens and abortifacients and should be avoided, especially in the first trimester. Azathioprine is a cytotoxic agent that appears to be much better tolerated in pregnancy.151,152

PSYCHIATRIC DISORDERS

Eating Disorders

The peak incidence of eating disorders matches that of those in the prime childbearing age range, so the likelihood of anorexia nervosa (AN) or bulimia nervosa (BN) complicating a pregnancy is high. The overall prevalence of AN is 0.5% to 1% of young adult women, with a mean age of onset of 17 years, and an overall prevalence of BN of 1% to 3% in the same population.137 Of all eating disorders, 90% begin before the age 25 years, and there has historically been an increased incidence of all eating disorder diagnoses in the past decade. The high incidence of amenorrhea in AN makes pregnancy less likely than in BN. Medical complications of AN include bradycardia, hypotension, orthostatic changes, hypothermia, mitral valve prolapse, and symptoms associated with electrolyte imbalance. Anemia and transaminitis are also seen.

Pregnancy can frequently precipitate a subclinical eating disorder or exacerbate a condition in remission. The loss of control of body image and weight gain are frequent inciting features for recurrence. Adverse pregnancy outcomes include increased rates of miscarriage, low birth weight, preterm birth, congenital malformations, and increased likelihood of cesarean section births.138 Inappropriate dieting, with subsequent folate deficiency, increases the rate of congenital neural tube defects. In the postpartum period, depression risk is increased threefold in mothers with a history of eating disorders.

Treatment of any eating disorder during pregnancy is aimed at the restoration of normal physiologic parameters, electrolyte replacement, and correction of ketosis. There are no recommended pharmacologic interventions for AN by the US Food and Drug Administration, but antidepressant therapy may be beneficial in those with exacerbations of BN.139

Substance Abuse

The prevalence of substance abuse in pregnancy has been increasing, with major societal and personal costs. Substance abuse is frequently not identified during pregnancy unless self-reported, or an unplanned pregnancy is discovered during the evaluation of the mother for a substance-related disorder. This is particularly common in the ED, where women of childbearing age are seen frequently for associated complications and pregnancy is coincidentally identified during the visit.

The overall rate of substance use and abuse in pregnancy is approximately 15%. The rate has been steadily increasing in the last 3 decades, with roughly 225,000 infants annually exposed to illicit drugs in utero.140 Drug use and dependence afflict women, regardless of socioeconomic status, ethnicity, or age. Although illicit drug use is more common in African Americans, alcohol, cannabis, and prescriptive drug use are most commonly seen in white women.

The impact of substance abuse on pregnancy is determined by the following: (1) specific exposure (mono- vs. polysubstance abuse); (2) gestational timing; (3) duration of exposure; (4) dosing of exposure; and (5) other maternal comorbid conditions (eg, smoking, general nutritional status). There is a strong association of substance abuse with psychiatric conditions, particularly depression and psychosis.

Within this context, the terms abuse and dependence will be used synonymously, although they are different clinical entities. Both conditions have the same impact on maternal and neonatal health and pregnancy-related complications.

Alcohol

Of women of childbearing age, 51% self-identify as alcohol users and 15% are binge drinkers.141 Nearly 2 million women annually are at risk for alcohol-exposed pregnancies, defined as women who are not using birth control, currently drinking, and are sexually active with a man.142 Once pregnancy has been identified, the rate of active alcohol consumption in gravid women drops to 7%, and binge drinking to lower than 2%.143

There is no clear safe threshold for alcohol intake during pregnancy, with intake as little as one drink/day being associated with increased rates of IUGR and low birth weight. Heavier consumption of alcohol at more than three drinks/day increases the rate of miscarriage, and more than five drinks/day significantly increases the risk of intrauterine fetal demise (IUFD) two to three times that of nondrinking mothers. Alcohol consumption in pregnancy is the most preventable cause of mental retardation, with alcohol-exposed children having a 1.7-fold greater relative risk of mental retardation and a 2.5 times greater risk of delinquent behaviors.

Congenital abnormalities associated with in utero alcohol exposure can be characterized within the fetal alcohol spectrum disorders. Fetal alcohol syndrome, the most severe of these, has a prevalence of up to 1/1000 births.143 It is characterized by at least one of a series of morphologic abnormalities in association with a history of heavy alcohol use (>three drinks/day), including midfacial hypoplasia, flat philtrum, low nasal bridge, epicanthal folds, shortened palpebral fissure, low-set ears, and microcephaly. It can also have ocular, cardiac, and skeletal manifestations.

Screening is imperative to identify at-risk pregnancies, and the most successful screening tools assume the presence of alcohol intake. This approach yields more honest reporting from the patient.144

Treatment of an alcohol-dependent mother is difficult. As with nonpregnant patients, withdrawal symptoms are likely to manifest 6 to 24 hours after last alcohol consumption. Any signs of withdrawal should prompt admission and continued management in an inpatient setting. There is a paucity of data on the risk of delirium tremens and major withdrawal in pregnant versus the nonpregnant population. There are also little data on the safety profiles of medications used to ameliorate withdrawal
The use of naltrexone, acamprosate, or disulfiram or the long-term use of benzodiazepines has not been studied in pregnancy.

**Smoking**

The long-term deleterious effects of smoking on fetal growth and development have been well documented, up to and including the risk of sudden infant death syndrome (SIDS). Chronic placental insufficiency and vasoconstriction lead to an increased risk of miscarriage, IUFD, preterm birth, IUGR, and clubfoot. Conversely, smoking decreases the risk of preeclampsia. Treatment for tobacco addiction in pregnancy is largely behavioral and cognitive. Nicotine patches have not been associated with adverse maternal or newborn consequences when used in the second and third trimesters.

**Cannabis**

Cannabis is the most commonly used illicit drug in pregnancy. Although marijuana use in pregnancy is not associated with any major congenital malformations or increased risk of IUFD, infants born to cannabis-using mothers show increased tremulousness, exaggerated startle responses, and high-pitched cries. These are some of the same features associated with neonatal abstinence syndrome (NAS) discussed later in more detail (see “Opioids”). Cannabis is excreted in breast milk and has been associated with neurologic impairment during continued exposure.

**Cocaine and Methamphetamines**

Maternal cocaine and methamphetamine use is independently linked to IUFD from impaired placental circulation and preterm birth (PTB) less than 36 weeks' gestation, preeclampsia, IUFD, and increased incidence of cesarean section, gestational hypertension, and GDM. Cocaine use also increases the risk of placental abruption and infarction. Infants of methamphetamine-addicted mothers have lower Apgar scores and increased rates of neonatal mortality and jaundice. The potential for adverse outcomes is increased in the presence of polysubstance abuse or other confounding maternal risks, such as poor nutrition. Neonatal congenital abnormalities do not seem to be significantly increased with cocaine use, although there is a slight increased risk of cleft palate with cocaine exposure.

Treatment of a gravid patient who is acutely intoxicated with cocaine or methamphetamine should involve the judicious use of benzodiazepines and antipsychotics, weighing the risk-benefit ratio for treatment against the medical and psychiatric instability of the patient. Methamphetamine is excreted in breast milk, so infant exposure continues after pregnancy.

**Opioids**

Roughly 1% of pregnant patients report opioid use during pregnancy, but drug testing proves this number to be higher, around 4%. In general, usage rates have been significantly increasing, which has created a downstream effect of large numbers of addicted infants requiring neonatal intensive care. There is a significant risk of unintended pregnancy among opioid-addicted women, close to 90%, compared to the unintended pregnancy rate in the general population of 40%. The ED is a likely site of entrance of the opioid-addicted gravid patient to the health care system.

There are no well-identified syndromes, congenital abnormalities, or teratogenic effects in infants of opioid-dependent mothers, but maternal risks of postpartum hemorrhage, PTB, and increased rates of cesarean section have been documented. Neonatal risks include IUGR, specifically symmetric smallness and small head circumference, and an increased risk of SIDS. The major complication in infants of opioid-addicted mothers is NAS, a constellation of physiologic and neurobehavioral changes noted in newborns of addicted mothers secondary to a sudden discontinuation of fetal exposure to abused substances. There has been a 10-fold increase in NAS within the last decade. These infants have a 97% admission rate to neonatal intensive care units.

The syndrome is characterized by the following: (1) CNS disturbances, including excessive or continuous high-pitched crying, shortened postprandial sleep pattern, hyperactive newborn reflexes, tremulousness, and increased muscle tone, myoclonic jerks, or frank convulsions; (2) metabolic and respiratory abnormalities (eg, sweating, hyperthermia, yawning, mottling, sneezing, nasal flaring, tachypnea); and (3) gastrointestinal disturbances (eg, increased sucking, poor feeding, regurgitation or projectile vomiting, loose or watery stools). The Finnegan scale, developed in the 1970s, is still the mainstay of neonatal assessment for NAS. Treatment of NAS is supportive.

**KEY CONCEPTS**

- The physiologic demands of pregnancy may cause previously occult medical conditions to become apparent and known problems to deteriorate rapidly.
- The physiologic adjustments of pregnancy alter the normal ranges for certain laboratory values. The adjusted values need to be considered in the interpretation of results.
- The possibility of pregnancy should be considered in the differential diagnosis of certain conditions, including new-onset seizures or status epilepticus ( eclampsia), glucose intolerance (GDM), persistent vomiting (hyperemesis gravidarum), and thyroid disorders.
- The immunosuppressive effects of pregnancy may cause temporary improvement in inflammatory and autoimmune conditions. This beneficial effect is lost in the postpartum period, resulting in exacerbations of asthma, thyroid disorders, and myasthenia gravis.
- Medication requirements can change drastically during pregnancy and the postpartum period.
- Certain medical conditions in the mother result in neonatal complications that require special resuscitative measures. This is particularly true of many chemical dependency states, and anticipatory management of these patients is essential.

179.1. A 28-year-old G2P1 at 26 weeks of gestation presents with a recurrent asthma flare. Vital signs are temperature, 36°C, heart rate, 110 beats/min, blood pressure, 120/60 mm Hg, respiratory rate, 28 breaths/min, and O2 saturation, 96%. She has diffuse inspiratory wheezes. Arterial blood gas reveals PaO2 = 90 mm Hg, PCO2 = 40 mm Hg, and pH = 7.34. Which of the following statements best describes the issues in management with this patient?

A. Corticosteroids are contraindicated.
B. Inhaled β-agonists are first-line therapy.
C. Most patients with asthma improve during pregnancy.
D. She has a metabolic acidosis.
E. Treatment and discharge are likely.

Answer: B. β-agonists followed by corticosteroids are the mainstay of asthma therapy during pregnancy. During pregnancy, one-third of asthmatics worsen, one-third improve, and one-third stay the same. Blood gas interpretation must take into account the so-called normal alkalosis of pregnancy, with a Pco2 of 30 to 32 mm Hg and a compensatory HCO3 level of 18 to 20 mEq/L. This patient has a relative hypoventilation and may indeed need admission for close observation.

179.2. Which of the following statements best describes treatment for hypertension in pregnancy?

A. Angiotensin-converting enzyme inhibitors are second-line agents.
B. Diuretics are contraindicated in the third trimester.
C. Hydralazine is a useful venodilator.
D. Labelatol is a first-line oral agent.
E. Sodium nitroprusside is the parenteral agent of choice.

Answer: D. First-line oral and parenteral agents are hydralazine and labelatol. The former is an arterial dilator. Most antihypertensives are useful in pregnancy; angiotensin-converting enzyme inhibitors and receptor blockers are the exception. Diuretics are second-line agents. Nitroprusside is a second-line agent due to concerns for fetal cyanide toxicity.

179.3. Which of the following statements best describes risk factors for acute myocardial infarction (AMI) and pregnancy?

A. Anemia is not a risk factor.
B. Gestational diabetes does not increase risk.
C. Hypotension is an important risk factor.
D. Maternal age is inversely associated with risk.
E. Maternal smoking increases the risk.

Answer: E. Maternal smoking increases the risk. AMI is rare but may occur. Up to 29% of cases have normal coronaries one their angiogram. Risk factors are anemia, diabetes, hypertension, old age, thrombophilia, and smoking. Atherosclerotic lesions are the more likely cause antepartum, whereas coronary dissection and vasospasm are more likely causes postpartum.

179.4. Which of the following statements best describes issues in the evaluation of diabetes mellitus in pregnancy?

A. Diabetic ketoacidosis (DKA) in pregnancy always presents with hyperglycemia and a low pH.
B. Patients with gestational diabetes usually require medical therapy to achieve adequate glycemic control.
C. Standard management of non–insulin-dependent diabetes in pregnancy is with continued use of oral medications.
E. The risk of malformations and pregnancy complications is significantly increased in patients with insulin-dependent disease as opposed to those with pre gravid, non–insulin-dependent diabetes.

Answer: D. The American Congress of Obstetricians and Gynecologists recommends universal screening for pregnant women to achieve prompt diagnosis and minimize related complications. Insulin-dependent diabetes mellitus (IDDM) and non–insulin-dependent diabetes mellitus (NIDDM) place the gravyda at increased risk for poor pregnancy outcomes, with the risk being related to inadequate glycemic control. Although patients with...
IDDM and NIDDM are typically managed with insulin during pregnancy, patients with gestational diabetes often achieve adequate control of their blood glucose level with diet alone. DKA is a potential complication of all forms of diabetes during pregnancy and may present with euglycemia and a minimal change in pH.

179.5. Which of the following statements best describes issues in the management of the pregnant patient with human immunodeficiency virus (HIV)?

A. Antiretroviral therapy is not appropriate in the first trimester of pregnancy with the exception of efavirenz, which is contraindicated.
B. Elective cesarean section is not indicated for all gravidas with HIV and a viral load greater than 1000 copies/mL.
C. Postnatal zidovudine therapy in the infant is necessary when the mother has received appropriate antepartum and intrapartum antiretroviral therapy and has a viral load less than 1000 copies/mL.
D. The risk of perinatal transmission of HIV is high in the setting of routine screening, intrapartum antiretroviral therapy, and elective cesarean section for patients with a viral load greater than 1000 copies/mL.

Answer C. Recommended care for HIV during pregnancy includes intrapartum antiretroviral therapy, postnatal zidovudine prophylaxis, standard treatment for opportunistic infections, and cesarean section for all patients with a viral load greater than 1000 copies/mL. It is appropriate to begin antiretroviral therapy during the first trimester, although it is recommended that these patients be managed by an infectious disease specialist. Postnatal zidovudine is recommended for all infants born to mothers with HIV.
CHAPTER 180
Drug Therapy in Pregnancy

Valerie A. Dobiesz | Daniel W. Robinson

PRINCIPLES

Background

More than 90% of women take at least one prescription or over-the-counter medication during pregnancy, and overall medication use during pregnancy has increased in the last 3 decades. One study revealed that only 22% of reproductive-aged women have pregnancy testing done when administered or prescribed US Food and Drug Administration (FDA) category D or X medications in the emergency department (ED). Unfortunately, research in the use of medications in pregnancy is currently insufficient to determine reliable and accurate risks to the mother and fetus. Only a few medications have been tested specifically for safety and efficacy during pregnancy and current methods to assess teratogenicity are limited in determining drug safety especially for newer agents. Prescribing medications during pregnancy is challenging and must account for the physiologic changes associated with pregnancy as well as the benefits and risks to the mother and to the developing fetus using all available data.

The fetal age at exposure is crucial in determining its impact on the pregnancy. The fetus is most vulnerable to toxic insults during the time of organogenesis (days 21–56 of fetal life). Exposure during this period may result in major anatomic defects. Exposure after the period of organogenesis may affect the growth and development of the fetus. Functional development of the central nervous system (CNS) is affected when it is exposed to a CNS teratogen during the 10th to 17th weeks of pregnancy.

Major birth defects affect 3% to 5% of all live births. Most are of unknown cause, but 1% to 3% of these are thought to be due to pharmaceutical or environmental agents. A teratogen is any chemical, pharmacologic, environmental, or mechanical agent that can cause disruptive development of the conceptus. Included in this definition are functional impairment, growth restriction, and congenital malformations. These may range from subtle neurobehavioral effects to devastating physiologic effects and physical deformities, including fetal death.

The process of establishing teratogenicity is tedious and often flawed. Animal research, although valuable in determining risk initially, is not always applicable to humans, and controlled prospective human studies are generally not performed for ethical reasons. As a result, much of our current knowledge on teratogenicity has been derived from less rigorous studies, which are inherently weak in establishing a causal relationship between a specific exposure and malformations. The genetic background of the fetus, timing and duration of the exposure, environmental factors, multiple exposures, nutritional deficits, maternal illness, and illicit drug use all contribute to the outcome of pregnancy. Large population studies are needed to understand the connection between the outcome of a pregnancy and in utero exposures. Finally, as in the case of diethylstilbestrol, teratogenicity may not be apparent for years after birth.

Classification of Teratogenic Risk

To aid physicians in determining the teratogenic potential of a particular medication, the US Food and Drug Administration (FDA) had assigned one of five letters—A, B, C, D and X—to the drug, depending on the strength of evidence for its safety or teratogenicity (Box 180.1). This classification system has been criticized as overly simplistic and perhaps inaccurate. Many believed that the classification system conveyed the incorrect impression that there is a gradation of reproductive risk from exposure across categories (ie, that risk increases from A to B to C to D to X) and that the drugs within a given category present similar reproductive risks. Efforts have been made to address these concerns and other significant gaps in knowledge. More than 90% of newly introduced drugs in the United States are assigned to class C, an undetermined teratogenic risk. The FDA issued a final rule for drug labeling during pregnancy, called the Pregnancy and Lactation Labeling Rule (PLLDR), effective June 2015, to address these concerns. The PLLR changes the content and format for prescription drug labeling to help health care providers assess the benefits and risks in counseling pregnant and nursing women who are taking medications. The rule requires the removal of letter categories and mandates labeling that includes a summary of risks of drug use during pregnancy and lactation, a discussion of the data supporting that summary, and any relevant information to help health care providers make informed decisions and counsel patients. Drugs already approved before this rule will be phased in gradually. Currently, a number of clinical teratology resources that assign risk are available online, such as Clinical Pharmacology, TERIS, and Micromedex REPRORISK (Shepard’s Catalog of Teratogenic Agents).

Drug Transfer Across the Placenta

Drug transfer across the placenta usually occurs by simple passive diffusion or protein transport. A thin layer of trophoblastic cells is all that separates maternal from fetal circulation. The degree to which a drug gains access to fetal circulation depends on molecular size, ionic state, lipid solubility, and extent of protein binding. Drugs with a molecular mass of less than 5 kDa readily diffuse. Anionic substances diffuse through the lipid layer more readily than ionized forms. Free drug diffuses more readily than a protein-bound drug. Because fetal pH is slightly more alkalotic than maternal pH, weak organic acids may become ion-trapped in the fetal circulation, increasing fetal exposure.

Drug Transfer During Lactation

Generally, drugs that are ingested or injected by the mother diffuse passively into milk and then back into the maternal circulation for excretion. The amount of drug diffusing into milk depends on many factors. Lipid-soluble and nonionic substances diffuse more readily, and highly protein-bound substances diffuse less
readily. Whether a substance is concentrated in maternal milk or not, the neonate generally is able to detoxify it with no adverse effects, and only a few drugs pose a serious danger to a breastfeeding infant.15 The interruption of breast-feeding should not be advocated except in rare situations of known drug toxicity to the infant and in all cases of maternal critical illness.

Drug Therapy During Pregnancy

In general, the health of the fetus is directly related to the health of the mother. Physicians should not withhold lifesaving medications from pregnant patients because of a reported risk to the fetus and should resuscitate pregnant patients according to advanced life support guidelines. Physicians may also prescribe any agent when the maternal benefits outweigh the risks to the fetus. Included in this category are therapeutic medications for asthma, arrhythmias, status epilepticus, life-threatening overdoses, and human immunodeficiency virus (HIV) infection. When prescribing drugs to pregnant and lactating women, one must weigh the benefits of treatment against the inherent risks of treatment or disease, consider the pharmacokinetics of the drug during pregnancy and lactation, choose the drug with the lowest known toxicity, and use the lowest effective dose.

PHARMACOLOGIC THERAPY

Analgesic Agents

Over-the-counter analgesics are used commonly during pregnancy, with acetaminophen being used by at least two-thirds of pregnant women.16 New evidence has been emerging that calls for a reassessment of the safety of these medications in pregnancy.17 Several studies have reported increasing use and adverse pregnancy outcomes with opioid use, such as neonatal abstinence syndrome and birth defects (Table 180.1).17-23

Acetaminophen

Acetaminophen (paracetamol) is widely used during pregnancy and has not been associated with congenital malformations.15,24-26 In a population-based, case-control study, acetaminophen was associated with a decreased risk of certain craniofacial malformations when it was used for febrile illnesses in the first trimester. Maternal acetaminophen use has recently been associated with a higher risk for hyperkinetic disorders and attention-deficit hyperactivity disorder—like behaviors in children, possible increased risk of cryptorchidism with early gestational exposure, and increased risk of childhood asthma with exposure in the first trimester.27-42 Acetaminophen is safe during lactation.15

Nonsteroidal Antiinflammatory Drugs

Prostaglandin synthesis inhibitors, such as nonsteroidal antiinflammatory drugs (NSAIDs), taken in the first trimester, have been linked to an increased risk of spontaneous abortions and a slight increase in cardiac septal defects, oral clefts, and gastrointestinal (an abdominal wall defect).15,24,26,43,44 When used in the third trimester, NSAIDs inhibit labor and have been used as tocolytic agents for premature labor. When used in the latter part of pregnancy, NSAIDs have been linked to a number of negative effects on the neonate, most notably premature closure of the ductus arteriosus, leading to neonatal pulmonary hypertension, and death. Recent studies have shown a potential association of exposure during pregnancy with an increased risk of asthma.15,45-46 An increased incidence of fetal periventricular hemorrhages, fetal nephrotoxicity, oligohydramnios, and neonatal gastrointestinal (GI) hemorrhage has also been reported.15,24,47 Use in the latter part of pregnancy is therefore discouraged. NSAIDs in general appear to be safe during lactation.

Aspirin

Chronic or high doses of aspirin during pregnancy should be avoided and may affect maternal and newborn hemostasis, leading to increased perinatal morbidity and mortality.15,44 Aspirin use may increase the risk of gastroesophageal reflux in the first trimester, intrauterine growth retardation (IUGR), and fetal and maternal hemorrhage in the third trimester. Aspirin use has been associated with postmaturity, prolonged labor, neonatal hypoglycemia, neonatal metabolic acidosis, premature closure of the ductus arteriosus causing primary pulmonary hypertension in the newborn, and neonatal death.15,24,48 Low doses of aspirin may be beneficial in pregnancies complicated by systemic lupus erythematosus with antiphospholipid antibodies and those at risk for gestational hypertension and preeclampsia, as well as fetuses with IUGR. Aspirin is excreted into breast milk and its use is discouraged during breast-feeding.15

Opiate Analgesics

In general, short-term, episodic use of opiates such as oxycodone, hydrocodone, morphine, and fentanyl appears to be safe in pregnancy. Their use near term, however, may result in severe respiratory depression of the neonate. In addition, prescribing of narcotics for long periods can lead to fetal addiction, low birth weight, and neonatal abstinence syndrome.21,24,44,48,49 Neonatal abstinence syndrome is characterized by CNS hyperirritability, autonomic nervous system dysfunction, and higher infant mortality.7,40,51

The short-term use of opiates during lactation appears to be safe, but nursing infants should be closely monitored for respiratory depression.15

Rapid Sequence Intubation Agents

Data regarding the use of these agents during pregnancy is limited and has primarily been obtained from animal studies and retrospective human data. None of the agents has been consistently associated with congenital malformations.7,15 The effects of nondepolarizing neuromuscular blocking agents on organogenesis in humans are not known, but are not thought to pose a significant teratogenic risk because very little of the maternal dose crosses the placenta (Table 180.2).15,24

BOX 180.1

US Food and Drug Administration Classification for Teratogenic Risk of Drugs

Class A: Controlled studies have shown no risk. Adequate well-controlled studies in pregnant women have failed to show risk to fetus.
Class B: No evidence exists of risk for humans. Animal studies show risk or are negative, but no human studies have been done.
Class C: Use may engender risk for fetus. Human studies are lacking, and animal studies may be positive or lacking. Potential for benefit may outweigh potential for harm.
Class D: Positive evidence of risk is based on studies or postmarketing data. Potential for benefit may outweigh potential for harm.
Class X: Drugs are contraindicated in pregnancy on the basis of human or animal studies or postmarketing reports that indicate benefit is clearly outweighed by risk.

Acetaminophen and birth defects (Table 180.1).17-23 pregnancy outcomes with opioid use, such as neonatal abstinence and has not been associated with congenital malformations.15,24-26

Acetaminophen is safe during lactation.15

Drug Therapy During Pregnancy

In general, the health of the fetus is directly related to the health of the mother. Physicians should not withhold lifesaving medications from pregnant patients because of a reported risk to the fetus and should resuscitate pregnant patients according to advanced life support guidelines. Physicians may also prescribe any agent when the maternal benefits outweigh the risks to the fetus. Included in this category are therapeutic medications for asthma, arrhythmias, status epilepticus, life-threatening overdoses, and human immunodeficiency virus (HIV) infection. When prescribing drugs to pregnant and lactating women, one must weigh the benefits of treatment against the inherent risks of treatment or disease, consider the pharmacokinetics of the drug during pregnancy and lactation, choose the drug with the lowest known toxicity, and use the lowest effective dose.
CHAPTER 180 Drug Therapy in Pregnancy

Maternal hemorrhage has been reported with alteplase and urokinase. Anticoagulants

Low-molecular-weight-heparin (LMWH) is preferred over unfractionated heparin and warfarin when indicated in pregnancy for therapeutic and prophylactic anticoagulation. Warfarin has the highest teratogenicity of the anticoagulants. The heparins, as a class, do not cross the placenta. All three anticoagulants are considered compatible with breast-feeding. Early reports on the use of heparin for the prevention or treatment of venous thromboembolism during pregnancy have noted an increased risk of prematurity, stillbirth, and fetal hemorrhage. However, these risks were recently attributed to the underlying maternal condition, rather than to heparin (Table 180.3).

Anticoagulants

Low-molecular-weight-heparin (LMWH) is preferred over unfractionated heparin and warfarin when indicated in pregnancy for therapeutic and prophylactic anticoagulation. Warfarin has the highest teratogenicity of the anticoagulants. The heparins, as a class, do not cross the placenta. All three anticoagulants are considered compatible with breast-feeding. Early reports on the use of heparin for the prevention or treatment of venous thromboembolism during pregnancy have noted an increased risk of prematurity, stillbirth, and fetal hemorrhage. However, these risks were recently attributed to the underlying maternal condition, rather than to heparin (Table 180.3).

Thrombolytic Agents

Alteplase, reteplase, urokinase, and streptokinase have been used successfully in pregnant women in cases of life-threatening pulmonary embolus, myocardial infarction, ischemic stroke, thrombosis of cardiac valve prosthesis, and deep venous thrombosis. Complication rates when used for these indications were similar compared to nonpregnant patients, and none of the live-born children had permanent defects. Experience with these agents during pregnancy, however, remains limited. To date, no teratogenic effects have been reported in humans, but intrapartum maternal hemorrhage has been reported with alteplase and urokinase.

Antidotes

There are limited human data on the risks of antidote use during pregnancy. Generally, antidotes should be used when there is a clear maternal indication to reduce the morbidity and mortality from the poisoning (Table 180.5).

N-Acetylcysteine

N-Acetylcysteine has been used successfully and without untoward effects in pregnant women who have overdosed on acetaminophen. No teratogenic effects have been reported, and pregnant patients who overdose on acetaminophen should be treated the same as nonpregnant patients. It is most likely safe during lactation because it has been used in neonates without untoward effects.

Deferoxamine

Deferoxamine has been associated with developmental effects on ossification in some animal species. Experience in humans is

CBD, Congenital birth defects; CP, crosses placenta; FDA, US Food and Drug Administration; IUGR, intrauterine growth restriction; LHS, limited human studies; NHT, no human teratogenicity; NOWS, neonatal opioid withdrawal syndrome; SAR, serious adverse reactions.

but hydroxycobalamin, like its related compounds, is considered compatible with breast-feeding.\textsuperscript{15,24}

**Methylene Blue**

Historically, methylene blue was injected into the amniotic sac to identify twins and detect rupture of the membranes, but these practices were associated with hemolytic disease in the newborn, hyperbilirubinemia, and deep blue staining of the newborn. Methylene blue in pregnancy has also been associated with an increased incidence of intestinal obstruction and atresia in the newborn. The effects of methylene blue on the nursing infant are expected to be minimal.\textsuperscript{15,24}

toxic alcohol poisoning, the benefits of treatment of the mother outweigh the possible risks to the fetus or nursing infant. Use of ethyl alcohol in these situations may be considered.\textsuperscript{15,24} Breastfeeding is not expected to continue during acute toxic alcohol poisoning.

**Hydroxycobalamin**

The effects of hydroxycobalamin on human pregnancy have not been studied, but benefits of its use in cyanide poisoning outweigh any risk to the fetus. Studies in animals do not reveal an association with any developmental abnormality. Breastfeeding is not expected to continue during cyanide poisoning but hydroxycobalamin, like its related compounds, is considered compatible with breast-feeding.\textsuperscript{15,24}
organophosphate poisoning, the benefits to the mother generally outweigh the possible risk to the fetus. Breast-feeding can be resumed after 6 to 7 hours after the last dose. 

Pyridoxine

Pyridoxine has not been associated with any adverse developmental effects when given in high doses, and it is safe in lactation. 

Succimer

Succimer has been linked to congenital defects in animal models, possibly because of its negative effects on zinc and copper metabolism. Experience with the use of succimer in human pregnancy is limited to case reports, and adverse effects are unknown. Breast-feeding is contraindicated in heavy metal poisoning. 

Antiinfective Agents

Infections during pregnancy have the potential to affect outcomes as well as fetal development adversely. In the first trimester,
infections are a common cause of spontaneous abortion and, in the second or third trimester, they are the most common cause of preterm labor and delivery. Antimicrobial agents may also adversely affect the pregnancy. Aminoglycosides, for example, may be nephrotoxic and ototoxic to the mother and newborn, tetracyclines may result in dental staining of the developing fetus, and lincosamides may be skeletotoxic.15,24 The penicillins, cephalosporins, and macrolide antibiotics remain the drugs of choice for infections during pregnancy. Alternative classes of antibiotics are prescribed only if these have failed to control the infection or in cases of severe maternal intolerance to these drugs. The choice of antimicrobial therapy will depend on the gestational age of the pregnancy, severity of infection, and maternal tolerance for the drug used. Many drugs are secreted into breast milk. Potential problems for the neonate include direct effects on the neonate, changes in bowel flora, diarrhea, and potential interference with culture results (Table 180.6).

**Antibiotics**

**Aminoglycosides**

The association of aminoglycosides such as gentamicin, streptomycin, tobramycin, and neomycin with nephrotoxicity and ototoxicity is well known in the literature and in practice.15,24 Aminoglycosides, however, do not appear to have any structural teratogenic effect in humans, but kanamycin and streptomycin have been reported to cause ototoxicity in the mother and her offspring. There are no reports definitively linking in utero exposure to gentamicin, streptomycin, tobramycin, and neomycin with ototoxicity or nephrotoxicity.15,27 Aminoglycosides are probably compatible with breast-feeding.

**Cephalosporins**

The first- to fourth-generation cephalosporins appear to be safe during pregnancy, although there have been no controlled studies examining their safety.15,24 Some cephalosporins are excreted into breast milk and may interfere with culture results in the evaluation of neonatal sepsis. Chloramphenicol. Chloramphenicol has been associated with bone marrow suppression and aplastic anemia, which may be fatal. Apart from these complications, its use during pregnancy appears to have no effects on the developing fetus. However, it is contraindicated at birth because chloramphenicol has been associated with cardiovascular collapse in the neonate, the so-called gray baby syndrome.15,24 The safety of chloramphenicol during breast-feeding is unknown. It is secreted into the breast milk, however and, because of its potential for bone marrow suppression and its association with gray baby syndrome, it is not recommended for use during lactation.

Clindamycin. Clindamycin has not been associated with birth defects in humans or in animal studies. The American Academy of Pediatrics (AAP) considers clindamycin to be compatible with breast-feeding, although there is a rare association with bloody diarrhea in nursing infants.15,24

Fluoroquinolones. Fluoroquinolones have been linked to numerous toxic effects on bone and cartilage growth in animal models and are discouraged from use during pregnancy, particularly during the first trimester. A number of observational studies, however, have failed to demonstrate such a toxic effect on the human fetus. Furthermore, a meta-analysis did not reveal any increase in the rates of spontaneous abortions, birth defects, prematurity, or low birth weight in women exposed to fluoroquinolones in the first trimester. The AAP considers ciprofloxacin to be compatible with breast-feeding.15,24 Data are inconsistent for other quinolones, and they are best avoided in lactation.

Linezolid. Linezolid has been linked to embryonic death, decreased weight, and abnormalities in cartilage and ossification in animal studies, but human data are lacking. Its use in pregnant women should be limited to cases in which the maternal benefits outweigh possible risks to the fetus.15,24 Linezolid is likely compatible with breast-feeding.27

**Macrolides**. Erythromycin, azithromycin, and clarithromycin are considered safe for use in pregnancy and compatible with breast-feeding, although there are no well-controlled studies examining their effects on the fetus. Some reports have linked erythromycin to pyloric stenosis, but the studies were not controlled.15,24 The estolate salt of erythromycin has also been associated with the development of hepatotoxicity in pregnant women and should be avoided. Clarithromycin has been associated with an increased risk of fetal and embryonic death, as well as with congenital malformations in animal species. This has not been shown in humans. In a prospective, controlled, multicenter observational study comparing the outcomes of pregnancies exposed to new macroles (including clarithromycin) with matched controls, no difference in the types or patterns of malformations between the groups was found. Azithromycin is poorly concentrated in breast milk and may be the preferred agent in lactating mothers.

**Metronidazole.** Metronidazole is mutagenic and carcinogenic in mice and rats. In humans, a number of studies have failed to demonstrate a clear association between metronidazole and congenital malformations when used in the first trimester of pregnancy. Metronidazole has been used during the second and third trimesters to treat bacterial vaginosis, with no untoward effects. However, because of its effects in mice, many physicians avoid prescribing it at all during pregnancy. The use of metronidazole during lactation is discouraged because of its potential mutagenic and carcinogenic effects in rats and its slow elimination from infants.15,24

**Nitrofurantoin.** Nitrofurantoin has traditionally been considered safe for use throughout pregnancy, except near term. However, a population-based, multicenter, retrospective case-control study associated its use in the first trimester to a number of congenital abnormalities. This association with congenital abnormalities has been refuted, however, and there are no confirmatory studies that show teratogenicity. Its use near term has been associated with hemolytic anemia in the newborn.15,24

**Penicillins.** The first- to fourth-generation penicillins and their derivatives (including procaine, benzathine, clavulenate, sulbactam, and tazobactam) are considered safe for use in pregnancy, as is oral probenecid.15,24 Penicillins are considered safe during breast-feeding, but their use may interfere with culture results if evaluation is required for a neonatal fever.

**Sulfonamides.** Sulfamethoxazole is commonly combined with trimethoprim and has traditionally been contraindicated in pregnancy because of an increased risk of neural tube defects and other congenital abnormalities, such as cleft palate. A number of observational studies have demonstrated an increased risk of cardiovascular and urinary tract malformations in the offspring of women treated with trimethoprim-sulfamethoxazole in the first trimester. Sulfonamides are contraindicated near term because of their association with kernicterus; they are excreted in

AAP, American Academy of Pediatrics; CP, crosses placenta; FDA, US Food and Drug Administration; G6PD, Glucose-6-phosphate dehydrogenase; LHS, limited human studies; LS, limited studies; NHT, no human teratogenicity. Additional data adapted from refs. 111 and 112.

breast milk and generally tolerated by a healthy neonate. They should be avoided, however, in ill or premature infants and in infants with hyperbilirubinemia or glucose-6-phosphate dehydrogenase deficiency.

**Tetracyclines.** Tetracycline and doxycycline readily cross the placenta. Tetracycline has been associated with the development of fetal fatty liver in pregnant women. It chelates calcium, causing abnormalities in bone growth and staining of decidual teeth. It has been associated with fetal genitourinary anomalies, inguinal hernias, and limb abnormalities. Tetracycline should therefore be avoided during pregnancy. Doxycycline, conversely, does not bind to calcium and is associated less with stained teeth than tetracycline. In addition, it does not appear to cause an increase in any type of congenital malformation. Despite these findings, doxycycline is not recommended in pregnancy.

Because tetracycline binds to breast milk calcium, only a small amount reaches the nursing infant, and it may be used for short periods (<10 days) during breastfeeding. Doxycycline does not bind to breast milk calcium and is present in greater quantities in breast milk. This could theoretically increase its side effects in the newborn. Its use in nursing infants is best avoided.

**Vancomycin.** Vancomycin has not been linked to birth defects in animals or in humans. Reports of auditory abnormalities and renal insufficiency in neonates of mothers treated with vancomycin are believed to be false-positives because these abnormalities were resolved on retesting. Vancomycin is excreted into milk but not well absorbed by the GI tract. Its effects on the nursing infant have not been studied.

**Antifungals**

Nystatin has a long safety profile during pregnancy and lactation. It is poorly absorbed from skin, mucous membranes, and the GI tract and is considered the antifungal agent of first choice for the treatment of mucocutaneous fungal infections. Clotrimazole, miconazole, and ketoconazole appear to be safe during pregnancy and lactation because they have not been associated with major birth defects. However, a minor increase in the incidence of hypoplastic left ventricle was reported in one case-control study. In addition, ketoconazole is teratogenic in rats. For these reasons, clotrimazole, miconazole, and ketoconazole are considered second-line treatment of fungal infections in pregnancy. Fluconazole is teratogenic in high doses (>400 mg/day) and has been associated with an increased incidence of craniofacial and cardiovascular defects in offspring and multiple abnormalities of the skeleton and cartilage. However, these anomalies were not noted when lower doses were used or with single-dose therapy (150 mg) for vaginal candidiasis.
Ketoconazole, fluconazole, and itraconazole are excreted into breast milk. Because of the safe use of ketoconazole in neonates and the lack of negative reports, it is considered compatible with breast-feeding (see Table 180.6). Antituberculous Agents

Untreated tuberculosis places the mother and fetus at greater risk than the use of antituberculous medications. Isoniazid, ethambutol, and rifampin cross the placenta and, in a review of antituberculous treatment during pregnancy, no association was found between these medications and major congenital malformations. Rifampin has been associated with hemorrhagic disease of the newborn. Despite this adverse effect, it is considered first-line therapy for the treatment of tuberculosis. All three antituberculous medications are considered compatible with breast-feeding (see Table 180.6).

Antiviral Agents

Antiviral Therapy

Acyclovir readily crosses the placenta and reaches higher concentrations in fetal circulation than in maternal circulation. Neither acyclovir nor valacyclovir has been associated with congenital malformations or adverse effects on the offspring. Intravenous (IV) acyclovir is the drug of choice for life-threatening maternal herpes simplex virus infections, such as disseminated disease, herpes encephalitis, and varicella pneumonia, which carries a maternal mortality of 44% if untreated. For non–life-threatening genital herpes infection in pregnant women, acyclovir or valacyclovir may be used. Experience with famciclovir is limited and therefore is not recommended for use in pregnancy. Because there are no reported adverse outcomes in infants of mothers taking acyclovir or in infants treated with acyclovir for disseminated herpes, it is considered safe during breast-feeding (see Table 180.6).

Antifungal Agents

Ketoconazole, fluconazole, and itraconazole are excreted into breast milk. Because of the safe use of ketoconazole in neonates and the lack of negative reports, it is considered compatible with breast-feeding (see Table 180.6). Antituberculous Agents

Untreated tuberculosis places the mother and fetus at greater risk than the use of antituberculous medications. Isoniazid, ethambutol, and rifampin cross the placenta and, in a review of antituberculous treatment during pregnancy, no association was found between these medications and major congenital malformations. Rifampin has been associated with hemorrhagic disease of the newborn. Despite this adverse effect, it is considered first-line therapy for the treatment of tuberculosis. All three antituberculous medications are considered compatible with breast-feeding (see Table 180.6).

Cardiovascular Agents

Antiarythmics

Atrial and ventricular arrhythmias are common during pregnancy. Most are benign; however, malignant degeneration occasionally occurs. All unstable tachycardias should be treated with electrical cardioversion and advanced cardiac life support guidelines. Stable patients may be treated medically, but the choice of drugs needs to be modified to protect the patient as well as the fetus from the drug’s harmful effects (Table 180.7).

Adenosine. Adenosine has been used safely throughout pregnancy and is the drug of choice for termination of maternal supraventricular tachycardia. Adenosine has also been used safely for termination of incessant tachycardia in the fetus. Adenosine is safe in lactation.

Amiodarone. Amiodarone is a class D agent containing large amounts of iodine and has been associated with congenital goiter and transient neonatal hyperthyroidism and hypothyroidism. Amiodarone has been linked to many congenital abnormalities, including growth restriction, structural cardiac abnormalities, corneal deposits, and developmental delay. It should be used only in refractory cases of supraventricular or ventricular tachycardias in the mother and incessant tachycardias in the fetus. Because of its high iodine content, excretion into milk, and long elimination half-life, amiodarone should not be used in nursing mothers.

Digoxin and Quinidine. Digoxin and quinidine are considered safe for use during pregnancy and lactation. Neither has been linked to congenital defects in humans or animals, and they are first-line agents for the treatment of significant maternal dysrhythmias. They have also been successfully used in fetal tachycardia. During lactation, digoxin appears compatible with breast-feeding; there is very little information about quinidine’s use in breast-feeding.

Lidocaine. Lidocaine rapidly crosses the placenta and becomes ion-trapped in the fetus. There is no evidence of a link between the use of lidocaine in the first trimester and any fetal developmental malformations. However, high doses used near term are associated with neonatal CNS depression, apnea, hypotonia, seizures, and bradycardia. Lidocaine is considered compatible with breast-feeding.

Procainamide. Procainamide has been safely used in the treatment of stable, wide-complex tachydysrhythmias during pregnancy. It has not been associated with fetal developmental abnormalities and appears well tolerated when used for a short duration. It has been associated with a high incidence of maternal antinuclear antibodies and the occurrence of a lupus-like reaction in humans. During lactation, procainamide and its metabolite, N-acetylprocainamide, have been found in breast milk and, although the AAP considers its short-term

CP, Crosses placenta; FDA, US Food and Drug Administration; IUGR, intrauterine growth restriction; LHS, limited human studies; NHT, no human teratogenicity.

use compatible with breast-feeding, other authorities do not recommend it.15,24

Flecainide. Flecainide has been used safely to terminate maternal and fetal tachycardia,5 but it has been associated with fetal hyperbilirubinemia, hepatotoxicity, and loss of fetal heart rate variability. Flecainide has also been found to be teratogenic in some animal species, resulting in cardiac and musculoskeletal abnormalities.5,24,25,29 The AAP considers flecainide compatible with breast-feeding, despite limited experience.

Ibutilide. There are only a few case reports of the successful and safe use of ibutilide during the latter part of pregnancy in humans.71-74 In animals, however, ibutilide was found to be teratogenic and caused cardiac septal defects as well as skeletal dysgenesis in rats, especially when high doses were given. Ibutilide should be reserved for refractory cases in which the benefits of therapy outweigh any fetal risk.15,24

Sotalol. Sotalol has been used in pregnant women to treat atrial arrhythmias successfully and safely, as well as hypertension. It has also been successfully used to terminate fetal atrial tachycardias.71,73 It does not appear to have teratogenic effects in animals. Some of the negative effects of sotalol include bradycardia in the newborn, persisting for 24 hours. Sotalol is concentrated in milk but does not appear to result in bradycardia or hypotension in the nursing infant and, according to the AAP, it is compatible with breast-feeding.15,24

Angiotensin-Converting Enzyme Inhibitors. Angiotensin-converting enzyme (ACE) inhibitors, classified as category D drugs, are contraindicated for use during pregnancy.74 Furthermore, ACE inhibitors are embryocidal in animals and increase the rate of stillbirths in some animal species. In humans, the most significant adverse fetal effects occur when used in the second and third trimesters.75,76 These include oligohydramnios, anuria, renal agenesis resulting in death, increased risk of stillbirth, intrauterine growth restriction, fetal skull abnormalities, pulmonary hypoplasia, respiratory distress syndrome, and fetal and neonatal hypotension.77 Captopril and enalapril are considered compatible with breast-feeding.15,24

Angiotensin II Receptor Antagonists. Angiotensin II receptor antagonists should be avoided during pregnancy because their use has been reported to result in fetal abnormalities similar to the abnormalities seen with ACE inhibitors, including renal agenesis, neonatal anuria, oligohydramnios, intrauterine growth restriction, persistent patent ductus arteriosus, abnormal ossification, and death.15,24,25,28 Their safety in lactation is unknown.

Beta Blockers. Beta blockers have become a first-line treatment of hypertension in pregnancy. They have not been associated with fetal malformations and appear to be safe when used for short periods. Adverse fetal effects include intrauterine growth restriction and a low placental weight. Beta blockers lacking intrinsic sympathomimetic activity, such as acesulfam, atenolol, nadolol, and propranolol, are more likely to be associated with these adverse effects. When beta blockers are given near term, they have been associated with persistent beta blockade in the newborn. Nonselective beta blockers, such as propranolol, also have resulted in neonatal hypoglycemia, respiratory depression, and hyperbilirubinemia in the newborn. These adverse effects

Antihypertensives

Labetalol is the agent of choice for hypertensive emergencies in pregnancy (Table 180.8).

</tbody>
</table>
Calcium Channel Blockers. Calcium channel blockers have been used for the treatment of hypertension and the termination of supraventricular rhythm disturbances during pregnancy. IV verapamil has also been used to terminate fetal tachycardia, and IV nicardipine has been used for severe preeclampsia. In addition, some calcium channel blockers, such as nifedipine and diltiazem, have been used as tocolytic agents. In laboratory animals, use of calcium channel blockers in the first trimester was associated with a dose-dependent increase in embryonic mortality and skeletal abnormalities. To date, however, these abnormalities have not been seen in humans, although data remain limited. Some complications of calcium channel blocker use during pregnancy include maternal hypotension, tachycardia, and fetal distress, especially pronounced when sublingual nifedipine or IV nicardipine is used.15,24 The AAP considers these drugs compatible with breast-feeding.

Diuretics

Loop diuretics such as furosemide are indicated in the treatment of pulmonary edema due to congestive heart failure. In laboratory animals, furosemide has been linked to renal and skeletal abnormalities when used in pregnancy. These effects have not been seen in humans, but a slightly increased risk of hypospadias has been reported. Furosemide is secreted into breast milk but is considered compatible with breast-feeding.15,24 Thiazide diuretics have been associated with hypoglycemia and electrolyte abnormalities in neonates when given near term and with an increase in meconium staining and perinatal mortality. Moreover, thiazide diuretics may have a direct effect on smooth muscle and inhibit labor. In general, these agents are considered safe during breast-feeding.

Nitrates. Nitroglycerin has not been shown to cause fetal harm in animal studies. Limited reports in humans have not shown any major effects on the fetus or neonate. Nitroglycerin is rarely used during pregnancy, but it appears to be a safe, effective, rapidly acting, and short-acting agent.79 Nitroprusside for the treatment of hypertensive emergencies in pregnancy has the same advantages and disadvantages as in nonpregnant patients. During prolonged administration of high doses, nitroprusside may result in cyanide toxicity and severe acidosis. It readily crosses the placenta, and fetal levels of cyanide can increase as high as twice maternal levels. Standard doses do not seem to subject the fetus to a major risk of toxicity but, with the availability of safer alternatives, notably labetalol, nitroprusside is considered a last resort agent.15,24,79 No data are available on its use during lactation, but breast-feeding is not expected to continue during a critical illness.

Clonidine. Clonidine has been safely used throughout pregnancy, but experience during the first trimester remains limited. It does not appear to be teratogenic in laboratory animals and does not increase fetal mortality. Transient neonatal hypertension has been reported in neonates.80 Its effects on breast-feeding neonates are unknown, but it is considered compatible with breast-feeding.15,24

Hydralazine. Hydralazine use has been associated with higher rates of maternal hypotension, placental abruption, and neonatal distress compared with labetalol. It is therefore no longer recommended as a first-line agent in the treatment of severe acute hypertension in pregnancy. It may still be used as a second-line agent. Hydralazine is considered compatible with breast-feeding.15,24

Methyldopa. Methyldopa has been safely used throughout pregnancy, and most reviews have not linked it to any teratogenic effects on the offspring or adverse effects on the pregnancy. Many emergency clinicians continue to prescribe it as first-line therapy for hypertension during pregnancy. Methyldopa is compatible with breast-feeding.15,24

Vaspressors

Vaspressors all have the potential to increase uterine vascular resistance, resulting in a proportional decrease in placental blood flow. At this time, on the basis of its safety profile, phenylephrine appears to be the vaspressor of choice in the treatment of vascular collapse during pregnancy (Table 180.9).79,91

Endocrine Agents

Diabetes Medications

Diabetes mellitus is associated with a number of congenital malformations involving multiple organ systems, as well as with a significant increase in perinatal morbidity. Glycemic control in

</tbody>
</table>

**Antimetics**

Nausea and vomiting occur in up to 80% of all pregnant women between 6 and 12 weeks of gestation, but these symptoms are usually self-limiting. One-third of women with nausea and vomiting of pregnancy have clinically significant symptoms, and 1% will progress to hyperemesis gravidarum, which poses health risks and pathogenesis of this condition associated with pregnancy is likely multifactorial (Table 180.12).82

**Antacids**

H2 Receptor Antagonists. Antacids are commonly prescribed throughout pregnancy. None of the H2 receptor antagonists has been linked to congenital malformation, and they all appear to be safe for the nursing infant. There are multiple reports in the literature, however, linking in utero gastric suppression to an increased incidence of asthma and allergies during childhood, which require confirmation.15,24,83

Proton Pump Inhibitors. Studies on proton pump inhibitor (PPI) use in pregnancy are limited but several studies and a meta-analysis have found no association with an increased risk for major congenital birth defects, spontaneous abortions, or preterm delivery.32,84,85 Esomeprazole, lansoprazole, pantoprazole, and rabeprazole may be used during pregnancy. There are reports, however, of an increased incidence of GI, hepatic, and thyroid cancers in rats and mice. Several studies have demonstrated a possible link between in utero exposure to gastric acid suppressors and childhood allergic disorders and asthma.15,24,83,96,97 There are no human data studying the effect of PPIs on nursing infants.

**Antiemetic Medications**

Nausea and vomiting occur in up to 80% of all pregnant women between 6 and 12 weeks of gestation, but these symptoms are usually self-limiting. One-third of women with nausea and vomiting of pregnancy have clinically significant symptoms, and 1% will progress to hyperemesis gravidarum, which poses health risks...
Chapter 180: Drug Therapy in Pregnancy

Malformations, although experience with the newer agents remains limited. Recent studies of ondansetron have suggested a low teratogenic risk; however, an increased risk for a cardiac septum defect is possible, but data are inconsistent, but this has not been confirmed in other studies. The AAP considers these agents compatible with breast-feeding.

**Neurologic Agents**

**Anticonvulsants**

Anticonvulsants are known teratogens, and 30% of neonates exposed to commonly used anticonvulsants exhibit congenital anomalies. The risks for birth defects increase with the duration of exposure and with the number of agents used. Valproate is associated with the most frequent serious adverse effects on the pregnancy and fetus (20.3% incidence of serious adverse outcomes) compared with phenytoin, carbamazepine, and lamotrigine (10.7%, 8.2%, and 1.0%, respectively). Despite the risks, most practitioners believe that it is important to control seizures during pregnancy. Generalized seizures during pregnancy are associated with an increased risk for spontaneous abortion, hypoxic injury to the fetus, and impaired neuropsychological functioning.

Monotherapy is the most appropriate option and is recommended at the lowest effective anticonvulsant dose. Dividing the

</table>

\(^a\) Several studies have shown a possible link between in utero exposure to gastric acid suppressors and childhood allergy and asthma. Additional data adapted from ref. \(^{116}\).

Daily dose to decrease peak plasma levels may be considered. Adjustment of the dosage upward is often required to maintain adequate seizure control. \(^{15,24}\)

**Classic Anticonvulsants.** The classic anticonvulsants are considered class D agents and are teratogenic. Carbamazepine has been linked to an increased risk of craniofacial defects, neural tube defects, and developmental delay. Phenobarbital has been associated with a slightly increased risk of congenital heart disease and cleft lip or palate. In addition, its chronic use during pregnancy has been associated with neonatal withdrawal. Phenytoin use during pregnancy has been associated with the fetal hydantoin syndrome, which affects 5% to 10% of pregnancies. This syndrome is characterized by varying degrees of ossification abnormalities of the extremities and digits, craniofacial abnormalities, including cleft lip and palate, impaired growth, delayed neurologic development, and multiple cardiovascular anomalies. Valproic acid is associated with multiple facial anomalies, neural tube defects, strabismus, and congenital heart defects. \(^{15,24}\)

Carbamazepine, phenobarbital, and phenytoin have also been associated with hemorrhagic disease of the newborn, presumably because they competitively inhibit placental transport of vitamin K. \(^{15,24}\)

Carbamazepine, phenytoin, and valproic acid are considered compatible with breast-feeding. Phenobarbital, on the other hand, has been associated with neonatal sedation and toxicity and is not advised during breast-feeding. \(^{15,24}\)

**Newer Anticonvulsants.** Newer anticonvulsants, such as lamotrigine, levetiracetam, and topiramate, have been associated with a slightly increased incidence of major birth defects, such as oral clefts, skeletal abnormalities, and hypospadias. The incidence of these birth defects increases significantly when these substances are combined with other anticonvulsants, such as valproic acid. \(^{15,24}\)

These findings, however, were not seen in two studies comparing the newer anticonvulsants. In the lamotrigine pregnancy registry, \(^9\) a study conducted by the manufacturer of lamotrigine, and in an observational study from Denmark, \(^9\) first-trimester exposure to lamotrigine, oxcarbazepine, topiramate, gabapentin, or levetiracetam was not associated with an increased risk of major birth defects.

These agents also appeared to be well tolerated by the nursing infant, except for topiramate, which caused excess sedation. \(^{15}\)

**Antipsychotics.**

These agents sometimes cause extrapyramidal side effects of the infants when exposed in utero. \(^{15,24}\) These effects are seen with use of the first- and second-generation antipsychotics. Haloperidol has been shown to cause some limb defects when the mother is exposed during the first trimester. However, this effect is not seen with other first-generation antipsychotics. \(^{15}\) Most second-generation antipsychotics do not show teratogenicity. However, there are insufficient data for all antipsychotics (Table 180.14).

**Migraine Medications**

**Ergot Alkaloids**

Neither ergotamine nor dihydroergotamine has been associated with teratogenic effects but are contraindicated in pregnancy
CHAPTER 180 Drug Therapy in Pregnancy

Asthma Medications

The prevalence of asthma in pregnancy is estimated at 8.8%, and one-third of pregnant asthmatics experience a worsening of their asthma that may progress to a critical asthma syndrome, including status asthmaticus and near-fatal asthma. Pregnant women with asthma are at risk for neonatal death, preterm birth, low-birth-weight infants, preeclampsia, and small-for-gestational-age infants. Asthmatic mothers may also have a higher rate of birth-weight infants, preeclampsia, and small-for-gestational-age infants. Asthmatic mothers are at risk for neonatal death, preterm birth, low birth weight, preeclampsia, and cataracts. Furthermore, their use in the third trimester has been linked to an increased incidence of preterm delivery, low birth weight, preeclampsia, and cataracts in the newborn. Other authors have also raised concerns about the development of congenital adrenal hyperplasia in newborns. Prednisone is considered safe during breast-feeding. Corticosteroids are the mainstay of therapy for acute exacerbations of asthma. Although they are not considered human teratogens, there may be a slightly increased incidence of orofacial clefts when oral steroids are used during the first trimester. Furthermore, their use in the third trimester has been linked to an increased incidence of preterm delivery, low birth weight, preeclampsia, and cataracts in the newborn. Other authors have also raised concerns about the development of congenital adrenal hyperplasia in newborns. Prednisone is considered safe during breast-feeding.

Data on the use of leukotriene antagonists in pregnancy are limited. One study has found no association with congenital abnormalities, but there was a slight increase in intrauterine hyperglycemia followed by insulin secretion may also occur, resulting in neonatal hypoglycemia, especially in diabetic patients. Terbutaline, when used IV or orally in pregnant women, may result in significant maternal and fetal arrhythmias, maternal pulmonary edema, and death. The FDA has recommended a label change to add a warning against its use in preterm labor because safer beta-agonists and tocolytic agents are available. Long-acting beta agonists also appear to be safe during pregnancy. Albuterol is compatible with breast-feeding. Ipratropium has not been found to be teratogenic in numerous animal models, but there are few data regarding its safety in human pregnancy. It is considered compatible with breast-feeding. Cromolyn sodium has not been associated with any significant risk of birth defects or negative perinatal outcomes. It is considered compatible with breast-feeding (Table 180.16).

Decongestants with strong vasoconstrictive properties, such as phenylpropanolamine, phenylephrine and pseudoephedrine, cause placental vasoconstriction and are not recommended during pregnancy. There are limited data suggesting that their use in the first trimester may result in an increased incidence of abnormalities typically associated with placental vascular disruption, such as gastroschisis and intestinal atresia. \(^\text{15,24}\) Recent evidence has supported the association of phenylephrine and endocardial cushion defect, phenylpropanolamine and ear defects, and phenylpropanolamine and pyloric stenosis with oral and intranasal decongestion use in the first trimester. \(^\text{102}\) The risk, however, appears to be low. The AAP classifies pseudoephedrine as compatible with breast-feeding.

**KEY CONCEPTS**

- Chemically induced birth defects are believed to be responsible for approximately 1% to 3% of anomalous births.
- Gestational age is crucial in determination of the impact of any given exposure, especially during organogenesis (days 21–56 of fetal life), when major body organs are formed.
- Human data on teratogenicity and fetal toxicity of medications is often limited, and causal associations are difficult to determine, especially with newer medications.
- In general, the health of the fetus is directly related to the health of the mother, and drugs should be given when the maternal benefits outweigh the risks to the fetus.
- Certain medications should be avoided during pregnancy, if possible, because they are known teratogens or cause potential toxic effects in the newborn; these include anticonvulsants, warfarin derivatives, NSAIDs, sulfonamides, fluoroquinolones, and ACE inhibitors.

CHAPTER 180: QUESTIONS AND ANSWERS

180.1 A 42-year-old woman who is 7 months pregnant presents with severe, pressure-like chest pain that occurred while she was washing her clothes. The pain radiates to both shoulders and is associated with dyspnea and dizziness. Vital signs show heart rate, 92 beats/min, respiratory rate (RR), 22 breaths/min, blood pressure (BP), 134/70 mm Hg, and O₂ saturation, 97% on room air. She appears pale and diaphoretic and has a substantial increase in urine output. Lung examination reveals equal breath sounds without rales, rhonchi, wheezes, or friction rubs. Cardiac examination reveals a regular rhythm at 92 beats/min.

There were no murmurs, gallops, or rubs appreciated. An electrocardiogram (ECG) shows ST elevations in leads I, aVL, and V₂–V₆, with reciprocal T wave inversions. Of the following, which would be the most appropriate?

A. Administer beta blockers.
B. Administer heparin drip, and admit the patient to the ICU for further observation.
C. Administer metoprolol, and admit the patient to the ICU for further observation.
D. Administer ibuprofen, and admit the patient to the ICU for further observation.
E. Administer aspirin, and admit the patient to the ICU for further observation.

E. Start nonsteroidal antiinflammatory drugs (NSAIDs), and schedule the patient for two-dimensional echocardiography.

**Answer:** C. The patient has an acute myocardial infarction (MI) and requires immediate reperfusion therapy. This may be accomplished by thrombolytic therapy or by performing a percutaneous coronary intervention (PCI). Of the choices given, only C provides reperfusion therapy. In this case, treatment of the life-threatening MI in the mother outweighs the possible dangers to the embryo or fetus.

180.2. A 23-year-old woman who is 6 months pregnant was well until earlier in the morning, when she experienced sudden onset of shortness of breath and right-sided sharp chest pain. The pain is worse on inspiration, although her dyspnea becomes worse with any activity. She is alert and appears in distress. Her pulse is 112 beats/min, RR, 32 breaths/min, and BP, 98/48 mm Hg. Her temperature is 100.8°F (32°C), and O₂ saturation is 92%. Lung examination reveals splintering of the respirations, with rales and wheezing on the right. Cardiac examination reveals tachycardia. No murmurs, gallops, or rubs were noted. Chest radiograph reveals elevated right hemidiaphragm but no infiltrates. ECG reveals generalized T wave inversions. Of the following, which would be most appropriate?

A. Administer a low-molecular-weight heparin subcutaneously, as well as oral warfarin sodium (Coumadin).
B. Administer intravenous ceftriaxone and azithromycin for clinical pneumonia.
C. Administer nebulized bronchodilators, and start prednisone.
D. Administer oxygen, schedule for a diagnostic study, and start heparin.
E. Place a central line, and start early goal-directed therapy for sepsis.

**Answer:** D. On the basis of the information provided, the patient most likely has a pulmonary embolus. The patient is hypoxic and requires oxygen administration and anticoagulation. This may be accomplished with heparin and Coumadin. Coumadin, however, is teratogenic and is contraindicated in pregnancy. The patient has accomplished with heparin and Coumadin. Coumadin, however, requires oxygen administration and anticoagulation. This may be most likely has a pulmonary embolus. The patient is hypoxic and...
CHAPTER 181

Labor and Delivery and Their Complications

Veronica Vasquez | Shoma Desai

PRINCIPLES

Births in the emergency department (ED) are rare. In most cases, patients in labor are triaged directly to the obstetric suite for urgent management, maintaining a continuum of care with their primary providers. Because some births are precipitous and obstetric resources may not be immediately available, the emergency clinician must possess the basic skills for intrapartum management of normal and abnormal deliveries. In addition, a general knowledge of postpartum care is required in case of the occasional out-of-hospital delivery.

Limitations of the Emergency Department

The ED is a suboptimal location for the management of a complicated delivery. Unlike the obstetric suite, the ED may be lacking in appropriate resources, such as tocodynamometry, intrapartum pressure monitors, vacuum extractors, and forceps. In addition, the obstetrician typically has prenatal care information, including accurate gestational dates, presence of placental anatomy, and prior documented obstetric complications, which helps optimize maternal and fetal outcomes. It is difficult, if not impossible, to obtain these data in the ED while preparing for imminent delivery. Finally, cesarean section may be indicated to ensure a successful delivery. This option is not performed in the ED except in dire perimortem circumstances.

Epidemiology of Emergency Delivery

In 2011, the perinatal mortality rate in the United States was 6.26/1000 live births at 28 weeks of gestation or more. Delivery complications and mortality occur with greater frequency in the ED, where the perinatal mortality rate is approximately 8% to 10%. There are multiple features of the high-risk ED delivery profile. The ED as a care environment is often selected by an obstetric population that subsequently may have unexpected complications. Psychosocial factors, such as drug or alcohol abuse, domestic violence, and lack of access to medical care, contribute to precipitous deliveries in pregnant women with little or no prenatal care. Antepartum hemorrhage, premature rupture of membranes (PROM), eclampsia, premature labor, abruptio placentae, malpresentation, and umbilical cord emergencies are overrepresented in the ED population.

Patient Transfer Considerations

Because of the high risk associated with ED delivery, patients should be transported to a facility that has obstetric and neonatal resources whenever possible. The transfer of a woman with an impending high-risk delivery to such a facility should be based on sound clinical and medicolegal judgment. Transfer, with an en route delivery, cannot only be disastrous for the mother and fetus, but also violates federal law. Further consideration should be given to the type of nursery and level of care that the neonate will require after delivery, particularly in preterm (<36 weeks of gestation) deliveries, in which interval transfer for a higher level of care may be necessary.

NORMAL DELIVERY

Initial Presentation

Although the epidemiology and high complication rate associated with ED births demand caution, most are normal deliveries. Knowledge of normal labor and delivery mechanics aids safe vaginal delivery and facilitates the identification of complications.

Whenever a woman in the third trimester of pregnancy seeks treatment in the ED, the possibility that she is in labor must be considered. A wide array of nonspecific symptoms may herald the onset of labor. Abdominal pain, back pain, cramping, nausea, vomiting, urinary urgency, stress incontinence, and anxiety can be symptoms of labor. After 24 weeks’ gestation, any medical assessment should include the mother and fetus because fetal viability becomes established near that time.

Distinguishing False From True Labor

Braxton Hicks contractions, or false labor, must be differentiated from true labor. After 30 weeks of gestation, the previously small and uncoordinated contractions of the uterus become more synchronous and may be perceived by the mother. Braxton Hicks contractions do not escalate in frequency or duration, in contrast to the contractions of true labor. By definition, these contractions are associated with minimal or no cervical dilation or effacement. Examination should also reveal intact membranes. Care not to rupture the membranes is important to avoid inducing labor prematurely. If the diagnosis remains in doubt, external electrical monitoring of uterine activity can rule out true labor. Any discomfort associated with false labor is usually relieved with mild analgesia, ambulation, or change in activity.

Unlike false labor, true labor is characterized by cyclic uterine contractions of increasing frequency, duration, and strength, culminating in delivery of the fetus and placenta. In contrast to Braxton Hicks contractions, true labor causes cervical dilation to begin, marking the first stage of labor.

 Bloody Show

At the onset of labor, the cervical mucous plug may be expelled, resulting in what is termed a bloody show. The bleeding associated with this process is slight (usually only a few dark red spots admixed with mucus) and is due to the increase in cervical vascularity that occurs in pregnancy. Bloody show is not a contraindication to vaginal examination for the determination of cervical
Presentation specifies the anatomic part of the fetus leading through the birth canal. In 95% of all labors, the presenting part is the occiput, or vertex. On digital examination, a smooth surface with 360 degrees of firm bony contours and palpable suture lines is noted. Palpation of the suture lines and the fontanels where they join allows the examiner to determine the direction the fetus is facing. Three sutures radiate from the posterior fontanel, and four radiate from the anterior fontanel (Fig. 181.5). The lateral margins are examined carefully for fingers or facial parts that indicate compound or brow presentations.

Stages of Labor

First Stage of Labor

The first stage of labor is the cervical stage, ending with a completely dilated, fully effaced cervix. It is divided into a latent phase, with slow cervical dilation, and an active phase, with more rapid dilation. The active phase begins once the cervix is dilated to 3 cm. Most women who deliver in the ED arrive while in the active phase of stage 1 or early stage 2 labor (Fig. 181.1). The duration of the first stage of labor averages 8 hours in nulliparous women and 5 hours in multiparous women. During this time, frequent assessment of fetal well-being is important, and continuous external electrical monitoring may help identify fetal distress, allowing for appropriate intervention.

The maternal examination provides a rough guide to gestational age. At 20 weeks’ gestation, the uterine fundus reaches the umbilicus. Approximately 1 cm of fundal height is added per week of gestation until 36 weeks. At that time, the fundal height decreases as the fetus drops into the pelvis (Fig. 181.2). These estimates help establish gestational age rapidly.

The maternal examination provides a rough guide to gestational age. At 20 weeks’ gestation, the uterine fundus reaches the umbilicus. Approximately 1 cm of fundal height is added per week of gestation until 36 weeks. At that time, the fundal height decreases as the fetus drops into the pelvis (Fig. 181.2). These estimates help establish gestational age rapidly.

The abdominal examination with Leopold’s maneuvers may confirm the lie of the fetus (Fig. 181.3). After labor has begun, Leopold’s maneuvers may not easily distinguish the lie due to uterine contractions. Other modalities of assessing the lie, such as ultrasonography, may be necessary if presentation remains in question.

The determination of the stage of labor depends on examination of the cervix. A sterile approach using sterile gloves, sterile speculum, and povidone-iodine solution is indicated to prevent ascending infection. On pelvic examination, the clinician should determine the following:

- **Effacement** refers to the thickness of the cervix. A paper thin cervix is 100% effaced.
- **Dilation** indicates the diameter of the cervical opening in centimeters. Complete, or maximum, dilation is 10 cm.
- **Position** describes the relationship of the fetal presenting part to the birth canal. The most common position of the head is occiput anterior.
- **Station** indicates the relationship of the presenting fetal part to the maternal ischial spines (Fig. 181.4).

If bleeding continues or is of a larger volume, more serious causes should be suspected, such as placenta previa and placental abruption, which are contraindications for a vaginal examination.

- **Presentation** specifies the anatomic part of the fetus leading through the birth canal.

In 95% of all labors, the presenting part is the occiput, or vertex. On digital examination, a smooth surface with 360 degrees of firm bony contours and palpable suture lines is noted. Palpation of the suture lines and the fontanels where they join allows the examiner to determine the direction the fetus is facing. Three sutures radiate from the posterior fontanel, and four radiate from the anterior fontanel (Fig. 181.5). The lateral margins are examined carefully for fingers or facial parts that indicate compound or brow presentations.
Fig. 181.3. Leopold’s maneuvers. A, The first Leopold maneuver reveals which fetal part occupies the fundus. B, The second Leopold maneuver reveals the position of the fetal back. C, The third Leopold maneuver reveals which fetal part lies over the pelvic inlet. D, The fourth Leopold maneuver reveals the position of the cephalic prominence (Adapted from Willson JR, et al: Obstetrics and gynecology, ed 9, St. Louis, 1991, Mosby.)

Fig. 181.4. Fetal stations. The level of the ischial spines is considered 0 station. The silhouette of the infant’s head is shown approaching station +1. (Courtesy Ross Laboratories, Columbus, OH.)

Fig. 181.5. Bony landmarks of the fetal skull. (Adapted from Willson JR, et al: Obstetrics and gynecology, ed 9, St. Louis, 1991, Mosby.)
When the clinician suspects rupture of membranes, a sterile speculum examination is performed. This may reveal pooling of amniotic fluid, a fernlike pattern when the fluid is allowed to dry on a microscope slide, and the use of Nitrazine paper, which should turn blue, indicating an alkaline amniotic fluid (pH > 6). Although vaginal blood, cervical mucus, semen, and infection can interfere with results, sensitivities of Nitrazine paper and ferning for the detection of amniotic fluid are nearly 90%.

Of note, if vaginal bleeding is evident, digital and speculum examination of the pelvis should be deferred until an ultrasound study can be obtained to rule out placenta previa.

Second Stage of Labor

The second stage of labor is characterized by a fully dilated cervix and accompanied by the urge to bear down and push with each uterine contraction. The median duration of this stage is 50 minutes in nulliparous women and 20 minutes in multiparous women, with the anticipation of a more rapid progression for low-birth-weight premature infants. A prolonged second stage of labor is associated with an increase in maternal complications, including postpartum hemorrhage, infection, and severe vaginal lacerations.

Antenatal Fetal Assessment. During labor and delivery, the identification of fetal distress and appropriate intervention can reduce fetal morbidity and mortality. There are currently three methods of assessing a fetus in utero: (1) clinical monitoring; (2) electrical monitoring; and (3) ultrasonography. External electrical monitoring and ultrasonography merit consideration for use in the care of women laboring in the ED. Both modalities provide real-time information that is helpful for the diagnosis of fetal distress and assistance with intrapartum decision making.

Electronic Fetal Monitoring. Electronic fetal monitoring uses tracings of the fetal heart rate and uterine activity. Documentation of organized cyclic uterine contractions helps confirm true labor and may help diagnose fetal distress. In combination with clinical data, this can portend fetal distress due to hypoxia and provide a window for intervention.

Uterine activity is measured transabdominally by a pressure transducer, creating a recording of the contraction frequency. Because the measurements are indirect, the strength of the contractions correlates poorly with the tracing. The tracings are position and placement sensitive.

Fetal heart rate tracings have several components that can be assessed—baseline heart rate, variability, accelerations, decelerations, and diagnostic patterns.

Baseline Heart Rate. This is the average fetal heart rate during a 10-minute period (in the absence of a uterine contraction) and is the most important aspect of fetal heart rate monitoring. Fetal bradycardia is defined as a baseline of less than 110 beats/min; fetal tachycardia is defined as a baseline rate of more than 160 beats/min.

Variability. This can be instantaneous (beat to beat) or long term (intervals ≥ 1 minute). Both types of variability are indicators of fetal well-being. Accelerations occur during fetal movement and reflect an alert mobile fetus. Decreased variability may indicate fetal acidemia and hypoxemia or may be a side effect of a wide array of drugs, including analgesics, sedative-hypnotics, phenothiazines, and alcohol.

Decelerations. Decelerations in fetal heart rate are more complicated and should be interpreted according to the clinical scenario. There are three types of deceleration—variable, early, and late (Fig. 181.6). These terms refer to the timing of the deceleration relative to the uterine contraction.

Variable and early decelerations are common and normally represent physiologic reflexes associated with head compression in the birth canal or intermittent cord compression. Variable decelerations that are persistent and repetitive usually indicate repeated episodes of umbilical cord compression. The resultant hypoxia and acidosis may cause fetal distress. Attempts to shift maternal and fetal weight off the umbilical cord by changing position are indicated. If variable decelerations continue, the situation warrants efforts to hasten the delivery or, if obstetric backup becomes available, to perform an emergency cesarean section.

Late decelerations are more serious and most often indicate uteroplacental insufficiency. The tracing contours are generally smooth, with the heart rate nadir occurring well after a maximal uterine contraction (typically, ≥ 30 seconds afterward). The lag, slope, and magnitude of late decelerations correlate with increasing fetal hypoxia. Late decelerations are particularly ominous in association with poor variability, nonreactivity, and baseline bradycardia. When these findings are present, immediate obstetric consultation for delivery is indicated to prevent further hypoxia.

Diagnostic Patterns. Finally, the emergency clinician should be aware of the significance of sinusoidal tracings. Tracings of this type have low baseline heart rates and little beat to beat variability. The sinusoidal tracing is an ominous finding that is often premorbid. The differential diagnosis includes erythroblastosis fetalis, placental abruption, fetal hemorrhage (trauma), and amnionitis.

Ultrasonography. In the third trimester or during labor, ultrasonography can provide crucial information pertaining to impending delivery. When a technician and radiologist are available, and if time permits, the gestational age, biophysical profile, amniotic fluid index, and a survey of fetal and placental anatomy may be obtained. The American College of Obstetricians and Gynecologists (ACOG) has published recommendations regarding the indications for ultrasonography in the third trimester (Box 181.1). The parameters of immediate interest in the ED are fetal viability (specifically in utero gestation and fetal heart rate), lie, and presentation. The use of bedside transabdominal ultrasonography by emergency clinicians to evaluate such parameters expeditiously continues to rise as this modality becomes increasingly available and operator skill improves. Transvaginal ultrasonography is relatively contraindicated in the peripartum period, particularly in the cases of PROM and placenta previa.

Delivery. As stage 2 of labor progresses, preparation for delivery should be under way. A radiant warmer should be available and heated. Neonatal resuscitation adjuncts should be available, including a towel, scissors, umbilical clamps, bulb suction, airway equipment (oxygen, bag-mask device with appropriate-sized masks, and tools for endotracheal intubation), and equipment to achieve vascular access. Most deliveries require only basic equipment to cut and clamp the umbilical cord, suction the

| Survey fetal anatomy. |
| Diagnose cord prolapse. |
| Diagnose cause of third-trimester bleeding. |
| Rule out placental abruption. |
mouth and nose, and dry and stimulate the infant. A nurse should be at the bedside to coach and provide reassurance to the mother.

The mother is placed in the dorsal lithotomy position and prepared for delivery. The Sims position, or left lateral position with knees drawn toward the mother’s chest and back to the physician, is also an acceptable position. The vulva and perineum are cleared and gently scrubbed with sterile water or saline. A repeated sterile examination to assess labor progression and confirm presentation may be performed. Firm digital stretching
of the perineum, particularly posteriorly, may prevent tears and lacerations later in delivery.

Controlled coordinated expulsion with coaching to sustain each push aids with crowning and delivery of the head. The most vulnerable moment is when the fetal head begins to stretch and distend the perineum. Instructing the mother to pant and not push slows the passage of the head and shoulders. The modified Ritgen maneuver may be used to support the perineum and prevent maternal injury. In this technique, a towel-draped, gloved hand is used to stretch the perineum and gently exert pressure on the chin of the fetus. The second hand places pressure on the occiput superiorly, guiding the head into slight extension and positioning it so that its smallest diameter passes through the pelvic outlet. Calm communication between the physician and mother is the best way to maintain control of the delivery.

After the head is delivered, the physician allows the head to rotate toward the maternal thigh and clears the fetal face and airway. Next, the shoulders, usually anterior shoulder first, clear the perineum. The shoulders often deliver spontaneously, with little effort by the physician. Gentle downward traction on the head promotes delivery of the anterior shoulder. A subsequent upward motion pulls the posterior shoulder through the pelvic outlet. If delay occurs in delivery of the shoulders, the potential for shoulder dystocia should be considered.

As the infant clears the perineum, attention focuses on the umbilical cord. The infant should be kept low or at the level of the perineum to promote blood flow into the infant from the placenta. The cord is clamped and cut. Clamps should be placed 4 or 5 cm apart, with the proximal clamp 10 cm from the infant’s abdomen. An adequate umbilical stump is important for venous access if the neonate requires resuscitation. Suctioning of the nose and mouth at this time may reduce secretions that can cause increased airway resistance.

The infant is now clear of the mother and can be wrapped in towels and moved to the warmer. Gentle drying with a towel and suctioning usually provide adequate respiratory stimulation. If not, flicking the soles of the feet and rubbing the back are other modalities. Apgar scores at 1, 5, and 10 minutes after birth should be documented.

Episiotomy. With a controlled delivery, routine performance of an episiotomy is not recommended. It should be performed only for specific indications, such as shoulder dystocia or breech delivery. An episiotomy should be done before excessive stretching of the perineal muscles occurs but near the time of delivery to avoid excessive bleeding. Common practice is to cut the episiotomy when the head is visible during a contraction and the introitus opens to a diameter of 3 or 4 cm. The literature currently recommends a mediolateral incision to avoid perineal tears and rectal involvement (Fig. 181.7).

Third Stage of Labor

The third stage of labor involves the delivery of the placenta and frequent checks of the tone and height of the uterine fundus. Signs of placental separation include the following: the uterus becomes firmer and rises; the umbilical cord lengthens 5 to 10 cm; or there is a sudden gush of blood. These signs usually occur within 5 to 10 minutes of the delivery of the infant but may extend to 30 minutes. Beyond 18 minutes, the risk of postpartum hemorrhage increases and is up to six times more likely after 30 minutes. Although the placenta may be delivered expectantly, active management reduces the length of the third stage of labor and thereby decreases the risk of postpartum hemorrhage. Active management includes the administration of uterotonic gentle traction of the clamped umbilical cord with mild pressure applied above the symphysis pubis and uterine massage after delivery. Any attempt to deliver the placenta before it separates is contraindicated.

Examination of the umbilical cord and placenta is an essential part of the delivery process and any abnormalities should be noted at this time. The umbilical cord is normally a three-vessel structure, with two umbilical arteries on either side of the single umbilical vein. A two-vessel cord (one umbilical artery) occurs in 1 of 500 deliveries and is more prevalent in African Americans. Common abnormalities of the placenta include accessory lobes and abnormal cord insertion. Visible clots adherent to the uterine aspect may indicate placental abruption and the discovery of an incomplete placenta or membranes should alert the emergency clinician to the possibility of postpartum complications.
Fourth Stage of Labor

The fourth stage of labor refers to the first hour after delivery of the placenta and is a critical period during which postpartum hemorrhage is most likely to occur. The cervix and vaginal fornices should be inspected for deep lacerations as a result of delivery, and repair of any vaginal lacerations should be performed at this time.

Finally, oxytocin is infused to promote contraction of the uterus and control hemorrhage. The uterus is evaluated frequently for tone and massaged transabdominally if any sign of relaxation exists. Oxytocin should not be given before delivery of the placenta because this could result in the trapping of placental fragments or may hinder the delivery of an undetected twin.

THIRD-TRIMESTER COMPLICATIONS ASSOCIATED WITH DELIVERY

Obstetric problems in the third trimester often result in the initiation of labor. Premature labor, PROM, and third-trimester bleeding are relatively common complications. The fundamental question to be addressed in these settings is whether the fetus would fare better in utero or delivered.

Premature Labor

Premature or preterm labor and fetal immaturity are the leading causes of neonatal mortality. Preterm labor is defined as uterine contractions with cervical changes before 37 weeks of gestation. Many underlying conditions result in preterm labor, which is associated with 5% to 18% of all pregnancies and is the leading cause of neonatal death. Factors linked to this problem include substance abuse, history of preterm delivery, multiple gestations, placental anomalies, infections, and lifestyle or psychosocial stressors (Box 181.2). The unexpected nature of premature labor often results in an ED visit. When delivery is not imminent, the patient can be moved to the obstetrics unit for further care.

Clinical Features

The diagnosis of preterm labor requires the identification of uterine activity and cervical changes before 37 weeks of gestation. Early maternal signs and symptoms include an increase or change in vaginal discharge, pain resulting from uterine contractions (sometimes perceived as back pain), pelvic pressure, vaginal bleeding, and fluid leak.

Diagnostic Testing

If uterine contractions and cervical changes are present, and the estimated fetal weight on ultrasonography is less than 2500 g, the diagnosis of premature labor is likely. The differentiation of false labor from true labor is best done by electrical monitoring. The initial evaluation of a woman with possible preterm labor includes urinalysis, complete blood count, and pelvic ultrasonography. If delivery is not imminent, these studies can be performed under monitoring in the ED or obstetrics area. Whenever possible, these patients should be transferred to a perinatal center with an associated intensive care unit.

Management

A viable fetus and healthy mother are indications for medical management directed toward the prolongation of gestation. Preterm labor should not be postponed with medical management in the cases of fetal compromise, major congenital anomalies, intrauterine infection, placental abruption, eclampsia, significant cervical dilation, or PROM.

The treatment of preterm labor involves multiple modalities and is usually performed outside the ED. Tocolytics and fetal maturation therapy combined with bed rest and hydration are used with the hope of prolonging pregnancy (Box 181.3). When tocolytics are indicated, they should be used in coordination with an obstetric consultant because their initiation may arrest preterm labor, delaying delivery for 48 to 72 hours. These patients optimally should be transferred to an appropriate center before delivery, whenever possible, because medical management fails in more than 25% of preterm patients for whom it is attempted. It is important to review the contraindications to tocolytics before initiation of these therapies (Box 181.4). Any patient receiving tocolytics should be monitored for signs of fetal distress.

BOX 181.2

Factors Linked to Preterm Labor

Demographic and Psychosocial
- Extremes of age (>40 yr, teenagers)
- Lower socioeconomic status
- Tobacco use
- Cocaine abuse
- Prolonged standing (occupation)
- Psychosocial stressors

Reproductive and Gynecologic
- Prior preterm delivery
- Diethylstilbestrol exposure
- Multiple gestations
- Anatomic endometrial cavity anomalies
- Cervical incompetence
- Low pregnancy weight gain
- First-trimester vaginal bleeding
- Placental abruption or previa

Surgical
- Prior reproductive organ surgery
- Prior paraendometrial surgery other than genitourinary (appendectomy)

Infectious
- Urinary tract infections
- Nonuterine infections
- Genital tract infections (bacterial vaginosis)

BOX 181.3

Commonly Used Tocolytic Agents

Magnesium sulfate
- IV bolus over 20 min
- 2–4 g/hr IV infusion

Terbutaline
- 5–10 mg PO q4–6h
- 0.25 mg SC q20min
- 10–80 µg/min IV

Ritodrine
- 10 mg PO q2–4h
- 10 mg IM q3–8h
- 0.05–0.35 mg/min IV infusion

Isoxsuprine
- 20 mg PO q6h
- 0.2–0.5 mg/min IV infusion

*Ritodrine and Isoxsuprine have been discontinued in the United States.
**Premature Rupture of Membranes**

**Clinical Features**

PROM is defined as rupture of the amniotic and chorionic membranes before the onset of labor. It affects 3% of all gestations. During pregnancy, the chorionic and amniotic membranes protect the fetus from infection and provide an environment that allows fetal growth and movement. The amniotic fluid is constantly exchanged by fetal swallowing and urination and umbilical cord transfer.

The word *premature* in PROM refers to rupture before labor, not to fetal prematurity. In 8% of PROM cases, the fetus is at or near term, and PROM may result in normal labor. When PROM occurs before 37 weeks, it is called preterm PROM and is associated with significant fetal morbidity and mortality. PROM is the inciting event in one-third of all preterm deliveries.

After the membranes rupture, the period from latency to the onset of labor varies. Longer latent periods are common earlier in pregnancy, and the latency shortens as gestational age increases. At term, labor is a desirable result of PROM, but with fetal immaturity, delivery would result in fetal complications.

**Diagnostic Testing**

The diagnosis of PROM can be established by the history and physical examination. In most cases, the patient suggests the diagnosis and usually is correct. The patient typically describes a spontaneous gush of watery fluid, followed by a mild persistent seepage. Urinary incontinence or excess vaginal or cervical secretions are occasionally confused with PROM.

Examination of women with potential PROM is performed under sterile conditions to prevent ascending infection. Direct digital examination of the cervix is avoided. The identification of amniotic fluid was previously discussed. Table 181.1 summarizes the bedside testing modalities available to confirm the diagnosis of PROM. Visualization of the cervix for a prolapsed cord or small fetal part is performed during the evaluation for effacement and dilation. Culture specimens for group B streptococci, *Chlamydia trachomatis*, and *Neisseria gonorrhoeae* should be obtained.

**Management**

When the diagnosis of PROM is established, management depends on several factors, including the gestational age and fetal maturity, presence of active labor, presence or absence of infection, presence of placental abruption, and degree of fetal well-being or distress. In all cases, fetal heart rate monitoring, obstetric consultation, and admission are indicated. In the immature fetus (24–31 weeks of gestation), the initiation of specific treatment decisions aimed at accelerating fetal maturity should be made in coordination with the receiving obstetrician. This includes the possible administration of corticosteroids to promote pulmonary maturation. Patients with PROM between 31 and 33 weeks’ gestation are usually managed expectantly and those at or beyond 34 weeks of gestation are generally delivered.

All patients with PROM should be assessed for intraamniotic infection. Infectious complications should be diagnosed and treated before the mother demonstrates overt clinical signs. Preterm PROM is generally treated with intravenous ampicillin, clindamycin, or erythromycin. Treatment of term PROM is indicated when the patient is positive for group B streptococcus or has not been tested.

**Chorioamnionitis**

Chorioamnionitis occurs when vaginal or cervical bacteria ascend into the uterus, instigating an inflammation of the chorion and amnion layers of the amniotic sac. It occurs in 1% to 10% of all deliveries; risk factors include prolonged labor, PROM, excessive vaginal examinations, and recent amniocentesis. Box 181.5 summarizes the findings and evaluation of chorioamnionitis. Chorioamnionitis may result in prolonged first- and second-stage labor and decreased responsiveness to oxytocin. Early aggressive treatment, even before evidence of infection occurs, decreases neonatal morbidity and delays delivery, allowing more time for fetal maturation.

**Vertical Transmission of Human Immunodeficiency Virus**

ED deliveries may involve women who are known to be positive for human immunodeficiency virus (HIV), in addition to women who are infected but have never been tested. The latter group generally includes pregnant women with little or no prenatal care who are at risk for precipitous delivery. In 2005, between 215 and 370 infants were born in the United States with HIV infection. Of these, approximately 30% were born to mothers undiagnosed with HIV infection before delivery. Transmission may occur in the antepartum, intrapartum, or postpartum (breast-feeding) period. Because intrapartum transmission accounts for up to 75% of vertically transmitted HIV infections, antiretroviral therapy on presentation, even while labor progresses, can decrease vertical HIV transmission. Risk factors for transmission include high viral loads, prolonged rupture of membranes, maternal drug use, vaginal delivery, and breast-feeding.
Advances in point of care testing for HIV has resulted in the ability to make a preliminary diagnosis in a patient with HIV in the ED. In November 2002, the US Food and Drug Administration approved the OraQuick Rapid HIV-1 Antibody Test (OraSure Technologies, Bethlehem, PA). With a median turnaround time of 45 minutes, this test realistically allows an emergency clinician to initiate intrapartum and neonatal antiretroviral therapy when the test result is positive. Serologic confirmation is recommended, but emergent interventions can proceed on the basis of the bedside result. It has been shown that immediate treatment during labor can significantly decrease vertical transmission to the newborn. Moreover, a positive HIV test result may, in some cases, allow a change in the method of delivery, because cesarean section decreases the rate of HIV transmission compared with vaginal delivery methods. Decisions regarding initiation of antiretroviral therapy, as well as mode of delivery, should be made in consultation with an obstetrician and neonatologist, when available.

Support are warranted. If the delivery proceeds in the ED, preparation for maternal and neonatal resuscitation should be made rapidly.

Knowledge of abnormal labor and its anatomy and physiology is important for the emergency clinician facing a complicated delivery. Intrapartum management skills will enable him or her to proceed with delivery in an efficient and capable manner.

## Dystocia and Malpresentation

Dystocia, or abnormal labor progression, accounts for one-third of all cesarean sections and half of primary cesarean sections. Because rapid surgical resolution is unavailable to the emergency clinician, intrapartum management skills are important.

Dystocia can be divided into three categories of causative factors. Labor fails to progress when there are problems related to: the pelvic architecture (the passage), fetal size or presentation problems (the passenger), and inadequate uterine expulsive forces. Although it is useful to consider these causes independently, dystocia is usually caused by a combination of factors. Presentation problems are particularly important because they become apparent during stage 2 of labor and require immediate action.

In order of increasing incidence, brow, face, shoulder, and breech presentations are the most common malpresentations (Table 181.2). True fetopelvic disproportion is much less common. Cesarean section is indicated when labor arrest or cord prolapse coexists with these presentations.

## Breech Delivery

Breech is the most common malpresentation, occurring in just less than 4% of all deliveries. Three types of breech presentation exist—frank, incomplete, and complete (Fig. 181.8; Box 181.6). The main mechanical problem with breech presentations is that the buttocks and legs do not provide a sufficient wedge, hindering cervical accommodation of the relatively larger head. In addition, because the presenting part does not occlude the cervical opening completely, umbilical cord prolapse may occur.

By convention, the presentation (frank, incomplete, and complete) is followed by the relationship of the fetus to the birth canal, with the fetal sacrum as a reference point. Correlated with this abnormal presentation are several factors, such as prematurity, multiparity, fetal abnormalities, prior breech presentation, polyhydramnios, and uterine abnormalities.

Overall, one-third of breech fetal deaths are believed to be preventable. Asphyxia is often due to umbilical cord prolapse or entrapment of the head. Other complications include labor arrest or brachial plexus injuries, and fetal head and neck trauma can occur if inappropriate delivery techniques are used. Scheduled cesarean section for these patients reduces the potential for an ED presentation. However, emergency clinicians should be prepared for vaginal delivery of breech presentations in the event of premature or unforeseen labor in the absence of immediate surgical services.

**COMPLICATED DELIVERY**

**Background**

Complicated deliveries, involving dystocia, malpresentation, and multiple gestations, are potentially life-threatening emergencies. The emergency clinician cannot solve these obstetric problems with cesarean section and will therefore face the prospect of an extremely high-risk vaginal delivery. As expected, these abnormal deliveries increase the risk of fetal and maternal complications. Aggressive attempts to obtain obstetric, neonatal, and anesthesia support are warranted. If the delivery proceeds in the ED, preparations for maternal and neonatal resuscitation should be made rapidly.

Knowledge of abnormal labor and its anatomy and physiology is important for the emergency clinician facing a complicated delivery. Intrapartum management skills will enable him or her to proceed with delivery in an efficient and capable manner.

## Dystocia and Malpresentation

Dystocia, or abnormal labor progression, accounts for one-third of all cesarean sections and half of primary cesarean sections. Because rapid surgical resolution is unavailable to the emergency clinician, intrapartum management skills are important.

Dystocia can be divided into three categories of causative factors. Labor fails to progress when there are problems related to: the pelvic architecture (the passage), fetal size or presentation problems (the passenger), and inadequate uterine expulsive forces. Although it is useful to consider these causes independently, dystocia is usually caused by a combination of factors. Presentation problems are particularly important because they become apparent during stage 2 of labor and require immediate action.

In order of increasing incidence, brow, face, shoulder, and breech presentations are the most common malpresentations (Table 181.2). True fetopelvic disproportion is much less common. Cesarean section is indicated when labor arrest or cord prolapse coexists with these presentations.

## Breech Delivery

Breech is the most common malpresentation, occurring in just less than 4% of all deliveries. Three types of breech presentation exist—frank, incomplete, and complete (Fig. 181.8; Box 181.6). The main mechanical problem with breech presentations is that the buttocks and legs do not provide a sufficient wedge, hindering cervical accommodation of the relatively larger head. In addition, because the presenting part does not occlude the cervical opening completely, umbilical cord prolapse may occur.

By convention, the presentation (frank, incomplete, and complete) is followed by the relationship of the fetus to the birth canal, with the fetal sacrum as a reference point. Correlated with this abnormal presentation are several factors, such as prematurity, multiparity, fetal abnormalities, prior breech presentation, polyhydramnios, and uterine abnormalities.

Overall, one-third of breech fetal deaths are believed to be preventable. Asphyxia is often due to umbilical cord prolapse or entrapment of the head. Other complications include labor arrest or brachial plexus injuries, and fetal head and neck trauma can occur if inappropriate delivery techniques are used. Scheduled cesarean section for these patients reduces the potential for an ED presentation. However, emergency clinicians should be prepared for vaginal delivery of breech presentations in the event of premature or unforeseen labor in the absence of immediate surgical services.
CHAPTER 181  Labor and Delivery and Their Complications

Labor and Delivery and Their Complications

From a breech presentation by tactile vaginal exam may be difficult. Whenever a fontanel is not identified on examination, a breech presentation should be suspected. It is helpful to remember that the face and skull have a complete circle of bone, whereas the anus is flanked by bone on only two sides.

If time permits, an ultrasound examination is indicated to distinguish the type of breech presentation, gestational age, fetal weight, and position of the fetal arms and neck. If the fetus has a hyperextended neck, vaginal delivery is associated with a high incidence of spinal cord injuries. If possible, labor should be delayed to allow cesarean section. Similarly, if the arms are over the head, they increase the dystocia when the head enters the birth canal.

Management

Premature infants in the breech position often deliver spontaneously without difficulty. As the infant comes to term, dystocia becomes increasingly common. With commitment to a vaginal delivery, knowledge of breech dystocia mechanics may allow atraumatic delivery. The key goals are to maximize the size of the passage and to minimize the dystocia of the after-coming head.

Box 181.7 summarizes the actions associated with successful vaginal breech delivery.

The Mauriceau maneuver is the use of the fetal oral aperture to flex the fetal neck and draw in the chin. Because fetal neck extension is associated with cord injuries and worsening dystocia, this maneuver is useful to ensure a successful vaginal delivery. This maneuver should only be attempted once the fetal elbows and chin have entered the pelvic inlet to avoid inducing the Moro reflex, in which fetal head flexion results in the arms being suddenly extended. During this maneuver, the fetal pelvis should be supported to avoid abdominal injuries. A generous episiotomy may be necessary to facilitate the maneuver in a full-term infant.

Shoulder dystocia is the second most common malpresentation, occurring in 1.4% of all deliveries. In contrast to a breech presentation, which may be diagnosed in the antepartum period, shoulder dystocia develops in the intrapartum period. Maternal and fetal factors are associated with shoulder dystocia. Maternal

Diagnostic Testing

Before labor, Leopold’s maneuvers facilitate the diagnosis of breech presentation. For the emergency clinician, however, active labor restricts the use of Leopold’s maneuvers, and a vaginal examination is required. The differentiation of a vertex presenta-

**Box 181.6**

**Breech Presentations**

**FRANK BREECH**
- 60%–65% of all breech presentations
- Hips flexed, knees extended
- Buttocks act as good dilating wedge
- Incidence of cord prolapse ≈ 0.5%

**COMPLETE BREECH**
- Least common; occurs in ≈5% of all breech presentations
- Hips and knees flexed
- Buttocks act as good dilating wedge
- Incidence of cord prolapse is 5%–6%

**INCOMPLETE BREECH**
- 25%–35% of all breech presentations
- Incomplete hip flexion, single or double footling
- Poor wedge
- Increased incidence of prolapsed cord (15%–18%)
PART V | Special Populations | SECTION TWO | The Pregnant Patient

The Pregnant Patient

The delivery is most likely when a directed sequential approach to each maneuver is used. A rapid resolution of shoulder dystocia is important to avoid fetal asphyxia and resultant central nervous system injury. Obstetric and neonatology assistance may improve the outcome, and aggressive attempts to obtain assistance are warranted.

Initial attempts to resolve shoulder dystocia involve increasing the anteroposterior diameter of the passage. An episiotomy may be used for fetal maneuvering by allowing access to the posterior shoulder. Anteriorly, draining the bladder with a Foley catheter can generate room.

The most important first step is to use McRoberts’ maneuver (Fig. 181.10). Maternal leg flexion to a knee-chest position may disengage the anterior shoulder, allowing rapid vaginal delivery to follow. This maneuver “walks” the pubic symphysis over the anterior shoulder and flattens the sacrum, helping the fetus pass through the birth canal, one shoulder at a time. This method, although requiring very little effort, is often successful in alleviating shoulder dystocia.

If McRoberts’ maneuver fails to free the anterior shoulder, the application of suprapubic pressure may accomplish this by forcing the anterior shoulder to slip beneath the pubis or posterior shoulder to retreat into the hollow of the sacrum. Digital pressure

Diagnosis Testing

Shoulder dystocia is diagnosed clinically by the inability to deliver either shoulder. The fetal head may appear to retract toward the maternal perineum, otherwise known as the turtle sign. Traction on the head extends and abducts the shoulders, increasing the bisacromial diameter and worsening the dystocia. Fig. 181.9 shows the normal and abnormal relationship of the shoulders to the birth canal and illustrates why the bisacromial diameter is an important element of fetal biometry.

Normally, the shoulders negotiate the maternal pelvis in sequential fashion, anterior shoulder first. With shoulder dystocia, both shoulders attempt to clear the maternal pelvis simultaneously. In addition to the turtle sign, examination often reveals that the fetal shoulders are on a vertical axis, rather than oblique. These findings, in combination with an arrested delivery, confirm the diagnosis of shoulder dystocia.

Management

When shoulder dystocia becomes evident, knowledge of intrapartum delivery maneuvers can be lifesaving. Successful vaginal delivery is most likely when a directed sequential approach to each maneuver is used. A rapid resolution of shoulder dystocia is important to avoid fetal asphyxia and resultant central nervous system injury. Obstetric and neonatology assistance may improve the outcome, and aggressive attempts to obtain assistance are warranted.

Initial attempts to resolve shoulder dystocia involve increasing the anteroposterior diameter of the passage. An episiotomy may be used for fetal maneuvering by allowing access to the posterior shoulder. Anteriorly, draining the bladder with a Foley catheter can generate room.

The most important first step is to use McRoberts’ maneuver (Fig. 181.10). Maternal leg flexion to a knee-chest position may disengage the anterior shoulder, allowing rapid vaginal delivery to follow. This maneuver “walks” the pubic symphysis over the anterior shoulder and flattens the sacrum, helping the fetus pass through the birth canal, one shoulder at a time. This method, although requiring very little effort, is often successful in alleviating shoulder dystocia.

If McRoberts’ maneuver fails to free the anterior shoulder, the application of suprapubic pressure may accomplish this by forcing the anterior shoulder to slip beneath the pubis or posterior shoulder to retreat into the hollow of the sacrum. Digital pressure
may be transabdominal, through the introitus (anterior shoulder), or through the episiotomy (posterior shoulder).

If the shoulders remain undeliverable, the next step is to use Wood’s corkscrew maneuver. In this process, the impacted shoulders are released through rotation of the fetus 180 degrees. Fetal rotation is achieved by pushing the most accessible shoulder in toward the chest. The fetal axilla can be snared with a digit, or a hand can be slid in along the fetal spine to sweep the hips and generate rotation. Wood’s corkscrew maneuver is difficult to perform but should be attempted before reaching for an arm.

If the fetus remains trapped and several attempts have failed to yield delivery, consideration of delivery of an arm is appropriate. A hand is introduced along the posterior aspect of the posterior shoulder. The posterior arm is swept across the chest, bringing the fetal hand up to the chin. Attempts to splint the humerus may prevent fractures and brachial plexus injuries. The fetal hand is grasped and pulled out of the birth canal across the face, delivering the posterior shoulder.

The mnemonic HELPER (Box 181.8) has been proposed to help keep these steps organized and facilitate a sequential approach. These steps successfully deliver almost all cases of shoulder dystocia.

### Face, Brow, and Compound Presentations

Face and brow presentations yield a larger engaging aspect of the fetal head and predispose to labor arrest. Although these abnormal presentations can be diagnosed with ultrasonography or Leopold’s maneuvers, most are discovered during labor by vaginal examination. Approximately 50% are discovered during the second stage of labor.

The engaging diameter of the head in vertex position is approximately 0.8 cm less than a face presentation and 1.5 cm less than a brow presentation. Face presentations are described with the chin as a reference point (eg, mentum anterior). Face presentation is managed expectantly. The obstetric adage—“if a face presentation is progressing, leave it alone”—is based on the fact that mentum anterior presentations usually deliver vaginally, and mentum transverse presentations frequently rotate to become mentum anterior. Brow presentations, occurring when the fetal head is partially flexed, also spontaneously convert to a vertex or face presentation in more than 50% of cases.

A persistent mentum posterior face and brow presentation cannot be delivered vaginally if the fetus is full term. The resultant labor arrest requires symphysiotomy or cesarean section. Prolongation of the second stage is the most common outcome of both these malpresentations at term. For the emergency clinician, this prolonged second stage may provide a window during which obstetric help may arrive.

Compound presentations are those in which an extremity enters the birth canal with the head or breech. Small and premature fetuses generally proceed to vaginal delivery without incident.

Labor arrest and umbilical cord prolapse are accepted indications for cesarean section in the setting of face, brow, and
compound presentations. Manipulation of a compound presentation, including attempts to reduce the hand or arm, increases the rate of cord prolapse. Therefore, manipulation attempts are contraindicated. Cord prolapse rates are 10% to 20%, even without manipulation. Close monitoring and careful examination are indicated.

**MULTIPLE GESTATIONS**

Due to the increasing use and availability of fertility treatments, the incidence of multiple gestation pregnancies has been increasing. In 2013, twin deliveries accounted for 33.7/1000 births in the United States. Because multiple gestation deliveries have a higher incidence of preterm labor and low birth weights, maternal and fetal complication rates are correspondingly increased.\(^1\)

**Diagnostic Testing**

Most women with multiple gestations have the situation identified well before the third trimester. In patients who have had little or no prenatal care, bedside ultrasonography allows for a rapid diagnosis. The stages of labor for twins and other multiple gestations are similar to the stages for a singleton. Of importance to the emergency clinician is a relatively short latent phase of labor, with rapid progression to the active phase. The active phase is usually longer, however, and may allow time for obstetric assistance to arrive.

Vertex twin A and vertex twin B occur in approximately 42% of deliveries. One of the twins presents in a nonvertex position in approximately 35% to 40% of cases.\(^1\)

**Management**

The presentation of twins is an important determinant for the safety of vaginal delivery. Twins who are vertex-vertex can be delivered vaginally, barring any other obstetric complication. If twin B is nonvertex, many obstetricians recommend cesarean section to prevent delivery-related complications for twin B. External cephalic version and breech extraction are possible maneuvers to facilitate precipitous vaginal delivery. Generally, if twin A is nonvertex, cesarean section is preferred. In such cases, efforts should be made to delay delivery until an operative approach can be used. Proceeding vaginally can result in the interlocking of twins, associated with a high mortality.\(^1\)

The interval between the delivery of twin A and twin B is variable. In most cases, twin B delivers in minutes. When twin B does not follow rapidly, in utero assessment is important to document fetal well-being. If fetal heart tracings are reassuring, the delivery of twin B (especially nonvertex) should not be hastened. Repeated ultrasonographic evaluation may also be used to confirm twin B’s presentation and well-being.

After every ED delivery, particularly deliveries that are precipitous or that occur in the out-of-hospital setting, the mother should be examined for the possibility of twins. Ongoing labor may be confused with postpartum cramping, only to have twin B and all the potential complications surprise the emergency clinician. This is particularly relevant for women with inadequate prenatal care and low-birth-weight infants.

**UMBILICAL CORD-RELATED EMERGENCIES**

Umbilical cord–related complications can occur in normal and abnormal deliveries. Immediate intervention is required to prevent fetal morbidity and mortality. The spectrum of cord-related emergencies includes prolapsed cord, nuchal loops of the umbilical cord, body coils, cord knots, and entangled cords in monoamniotic twins. The cord length is believed to be proportional to fetal activity in utero during the first and second trimesters. Excess cord length increases the potential for umbilical cord complications of all types. Because the umbilical cord supplies the fetus with all its oxygen, interruption of cord circulation before establishment of fetal respiration is a life-threatening emergency. Fetal asphyxia caused by cord circulation compromise is potentially preventable with appropriate delivery interventions.

**Umbilical Cord Prolapse**

**Clinical Features**

Umbilical cord prolapse occurs when the umbilical cord precedes the fetal presenting part or when the presenting part does not fill the birth canal completely. Most cases of cord prolapse are unexpected and develop during the second stage of labor.

Cord prolapse has a variable rate of association with different fetal presentations. Compound, shoulder, and breech presentations yield gaps and a relatively poor dilating wedge. Table 181.3 summarizes the rates of umbilical cord prolapse with various fetal presentations. Malpresentations account for 50% of all cord prolapse cases and the prolapsed cord itself may be the first indication of a malpresentation. The reported incidence of cord prolapse ranges from 1.4 to 6.2/1000 deliveries, and associated perinatal mortality is estimated to be just below 10%.\(^1\)

**Diagnostic Testing**

Umbilical cord prolapse may be overt or occult, requiring a pelvic examination to reveal the umbilical cord lying beside the presenting part. The diagnosis may also be made with Doppler ultrasonography. In most cases, the diagnosis is obvious, and the cord is encountered at the perineum or introitus.

**Management**

When a prolapsed cord occurs with a viable infant, cesarean section is the delivery method of choice. If surgical delivery is available, maneuvers to preserve umbilical circulation should be instituted immediately. The mother should be placed in the knee-chest position, with the bed in the Trendelenburg position, because the presenting part is manually elevated off the umbilical cord. It is crucial that the mother be instructed to refrain from pushing to avoid further compression of the cord. Placement of a Foley catheter and instillation of 500 to 750 mL of saline into the bladder may help lift the fetus off the cord, particularly during the first stage of labor.\(^1\)

Preparation for an emergency cesarean section should be under way. The time from prolapse to surgical intervention is an

important factor in fetal outcome. Perinatal mortality rates are significantly higher for out-of-hospital cases versus those within a monitored setting, and outcomes correlate with time from diagnosis to delivery.

If timely surgical delivery cannot be performed, funic reduction—manual replacement of the cord into the uterus—and rapid vaginal delivery may be necessary. The same maneuvers to decrease cord compression should be used, pushing gently on the cord in a retrograde fashion, above the presenting part. Manipulation and cord trauma should be kept to a minimum because resultant vasospasm can cause fetal hypoxia. After funic reduction, the development of umbilical cord body coils or nuchal loops is common and should be anticipated.14

Cord Entanglement
The umbilical cord can also become entangled with itself, spontaneously knotting. Umbilical cord knots are related to intrauterine movements in early pregnancy. Approximately 5% of stillbirths are found to have knots that are believed to have caused fetal demise. Despite this association, cord knots can persist without problems as long as perfusion is maintained.

Loose umbilical cord knots pulled tight at delivery may cause fetal distress. As with cord prolapse, this situation must be resolved quickly to prevent fetal asphyxia. Rapid delivery with avoidance of further cord traction optimizes fetal outcome. No specific interventions have been identified to deal with this problem.

Long umbilical cords are associated with true knots, as well as with entanglements and prolapse. Umbilical cord loops can be single or multiple and can occur around the neck or body. Because the fetal limbs are short and flexed in most presentations, they are rarely involved. Although generally benign, umbilical cord loops may result in fetal complications, such as nonreassuring fetal status and respiratory distress.

During delivery, loose nuchal cords should be reduced at the perineum. Loose body coils usually disentangle spontaneously. The reduction process may be aided by slipping them over the extremities or forward over the head. On occasion, loops are tight enough to impede delivery and cannot be reduced. The solution is to cut the clamped cord and deliver the infant rapidly. The high frequency of nuchal loops (one in five births) means that the emergency clinician should expect to encounter this problem.

MATERNAL COMPLICATIONS OF LABOR AND DELIVERY
Maternal complications of labor and delivery include postpartum hemorrhage, uterine inversion and rupture, amniotic fluid embolism, and infections. Although some are managed medically, severe complications threaten the reproductive future and life of the mother, thereby requiring emergent surgical intervention.

Postpartum Hemorrhage
Clinical Features
Postpartum hemorrhage is the most common complication of labor and delivery. Defined as hemorrhage of more than 500 mL after vaginal delivery, it affects 5% to 10% of all deliveries and accounts for up to 25% of obstetric deaths. Postpartum hemorrhage is divided into two categories; the primary category includes blood loss that occurs within the first 24 hours, and the secondary category is hemorrhage 24 hours to 6 weeks after delivery. The clinical picture is as expected with any type of hemorrhage although, because of maternal adaptations during pregnancy, the patient may not show signs of shock until more than 1500 mL of volume has been lost.

Differential Diagnosis and Management
The differential diagnosis of primary postpartum hemorrhage includes uterine atony, genital tract trauma, retained placental tissue, and coagulopathies, or the “four Ts”—tone, trauma, tissue, and thrombin.

Uterine Atony. Accounting for 75% to 90% of cases, the most common cause of serious immediate postpartum hemorrhage is laxity of the uterus after delivery. Normally, postpartum bleeding from the placental implantation site is limited by contraction of the myometrium, constricting the spiral arteries. If the uterus does not contract, ongoing hemorrhage will occur. Predisposing factors include overdistention of the uterus (eg, multiple gestations, fetal macrosomia, polyhydramnios), prolonged labor, chorioamnionitis, use of tocolytics, and general anesthesia with halogenated compounds. As a diagnosis of exclusion, a physical examination to rule out obstetric trauma and retained products of conception should be performed before the diagnosis is reached. On examination, the uterus is palpable as a soft boggy mass.

After other causes have been excluded, therapy to augment myometrial contractions is instituted to prevent further hemorrhage. A two-handed uterine massage may stimulate uterine contractions. One hand exerts pressure transabdominally while the other supports the uterus through the introitus. Uterotonic in conjunction with massage usually provide enough stimuli to control bleeding. Blood is typed, crossmatched, and available for resuscitation should these measures fail.

Maternal Birth Trauma. Maternal birth trauma is the second most common cause of postpartum hemorrhage, accounting for up to 20% of cases. Associated factors include uncontrolled delivery, macrosomia, episiotomy, nulliparity, maternal coagulopathy, operative delivery, prolonged second stage of labor, preclampsia, and malpresentation. Tears and lacerations may involve the perineum, rectum, cervix, vagina, vulva, and urethra. Blood vessels beneath the vulvar or vaginal epithelium can also be injured without frank hemorrhage, resulting in the formation of large contained hematomas. These hematomas may go unrecognized for hours, gradually enlarging and possibly resulting in hemorrhagic shock. Delayed postpartum hemorrhage at these sites can also occur and is often a diagnostic challenge. The physical examination may reveal uterine displacement (lateral or cephalad), and confirmation by radiologic means may be used in stable patients. Management, decided in conjunction with specialists, may be expectant, involve bedside repair with absorbable suture, or require vascular embolization or surgical intervention, depending on the severity of clinical presentation.

Tears are classified by depth. First-degree tears involve the perineal skin and vaginal mucous membranes only. Second-degree tears extend through the skin into the fascia and muscles of the perineal body. Third-degree tears extend into the anal sphincter, whereas fourth-degree tears extend through all layers, including the rectal mucosa. Third- and fourth-degree tears should be repaired by an obstetrician in the operating room.

Retained Products of Conception. Approximately 10% of postpartum hemorrhage cases are due to retained placental tissue. Normally, the plane of cleavage between the zona basalis and zona spongiosa results in a clean separation of the placenta from the uterus. When this occurs, the placental tissue delivers as a single unit, without evidence of fragmentation. Any placental defect or evidence of accessory placental tissue may signify a retained cotyledon (part of the embryo). Retained fragments prevent myometrial constriction and result in hemorrhage. Aggressive traction on the placenta during stage 3 of labor can
result in retained products of conception, which may cause immediate or delayed postpartum hemorrhage. Ultrasound may reveal an expanded endometrium or solid echogenic mass within the uterus, providing evidence of retention.

Treatment requires removal of the remnant placental tissue. Digital uterine exploration with blunt dissection of the fragments from the myometrium will also facilitate myometrial contractions. Abnormally adherent tissue will not be freed by this maneuver.

The terms *placenta accreta*, *placenta increta*, and *placenta percreta* describe various degrees of abnormal placental attachment to the uterus. When the placenta adheres to the myometrium without the intervening decidua basalisis, it is termed *placenta accreta*. In *placenta increta*, the villi extend into the myometrium. In *placenta percreta*, the placenta penetrates the full thickness of the myometrium.

The current incidence of *placenta accreta* is approximately 3/1000 deliveries, a relative increase from past decades. Associated risk factors include multiparity, prior cesarean sections, placenta previa, previous curettage, and uterine anomalies.

**Coagulopathies.** All women with severe postpartum hemorrhage should be evaluated for disseminated intravascular coagulation (DIC). DIC can occur as a consequence of placental abruption, eclampsia, amniotic fluid embolism, postpartum infections, and dilution of clotting factors caused by aggressive volume resuscitation. Also, retained products of conception and dead fetal tissue contain excess thromboplastin, which can precipitate DIC. As with DIC from nonobstetric causes, bleeding is associated with hypofibrinogenemia, thrombocytopenia, and elevated levels of fibrin split products and D-dimer.

Appropriate management entails hemodynamic support and correction of coagulopathies. Recent investigations have reported the successful use of recombinant factor VIIa for severe cases of postpartum hemorrhage.

**Uterine Exploration and Removal of the Placenta.** In the presence of ongoing hemorrhage and retained products of conception, attempts to remove the placenta manually are indicated. The procedure entails risk of infection, perforation, and increased hemorrhage but may be the most expeditious way to control bleeding. Before beginning, the patient is placed on a monitor, good vascular access is established, and blood products are available. Also, a Foley catheter may be placed to reduce bladder distention and monitor urinary output. The umbilical cord is traced through the cervical os to the placenta, allowing the identification of a placental margin. The placental membranes are digitally perforated, and the placenta is gradually divided from the myometrium. After removal of the placenta, the uterus is explored for retained cotyledons. Removal of fragments that are still present may require curettage of the uterine cavity by an obstetrician.

Placenta accreta, percreta, and increta may be diagnosed in this setting or after curettage. Removal of fragments that are still present may require curettage of the uterine cavity by an obstetrician. Placenta accreta, percreta, and increta may be diagnosed in this way because they are not digitally dissectible.

Once it is emptied, the uterus should be stimulated to contract with uterine massage, oxytocin, and prostaglandins. Prophylactic antibiotic administration at the time of manual placenta extraction has been debated somewhat in the literature. If used, a single dose of metronidazole and ampicillin or cefazolin may be given.

**Uterine Packing.** For the emergency clinician, this technique may be used to create tamponade, preventing further blood loss. The procedure has limited morbidity and is straightforward. The emergency clinician introduces 15 to 20 yards of 4-inch gauze with a ring forceps and packs it into the uterus by a layering technique. Another option is to place a Foley catheter or Sengstaken-Blakemore tube into the uterus and instill the balloon with saline.

Opponents of packing have pointed out that an atonic uterus may accommodate a large volume of packing without effective tamponade. Packing may also increase the risk of postpartum infection, even when prophylactic antibiotics are given. As with all uterine manipulation and instrumentation, some risk of perforation also exists. Because pelvic embolization and hysterectomy sometimes are not immediately available to the emergency clinician, the importance of uterine packing as a temporizing measure is increased.

**Pelvic Vessel Embolization.** Pelvic bleeding postpartum can be difficult to control. Hysterectomy as a solution results in infertility and brings with it all the complications of general anesthesia and major surgery. Embolization of bleeding vessels by an interventional radiologist is another option. The procedure does not require an anesthesiologist, operating room, or obstetrician and may be readily available on an emergent basis. Reported success rates of embolization in control of postpartum hemorrhage range from 95% to 100%. Common sites of bleeding include the uterine artery, pudendal artery, and hypogastric artery. Because only the smallest involved branches are embolized, and recanalization usually occurs, future reproductive capability is generally preserved.

**Uterotonic Agents.** Although they are commonly applied on delivery of the placenta, uterotonic agents also have special application in the case of a postpartum hemorrhage. Uterotonic such as oxytocin, ergot alkaloids, and prostaglandins control bleeding by inducing myometrial contractions. Oxytocin is considered to be first-line treatment, given intramuscularly or intravenously. Ergot alkaloids, such as methylergonovine and ergotamine, may induce hypertension and are therefore contraindicated in patients with preeclampsia or other comorbid conditions. Finally, prostaglandins may also be used (eg, misoprostol), although they have shown no clear advantage over oxytocin or ergot alkaloids in published reports.

**Hysterectomy.** Rarely, hemorrhage continues, despite the interventions outlined. In the case of life-threatening obstetric bleeding, an emergency hysterectomy should be performed.

**Uterine Inversion Perspective**

Uterine inversion is an uncommon but serious complication of delivery that occurs during stage 4 of labor. The resultant postpartum hemorrhage can be severe and life-threatening, accounting for a maternal mortality rate of up to 15%. Uterine inversion complicates 1 in 2000 deliveries. Risk factors include excessive fundal pressure during delivery, forceful traction on the umbilical cord (especially in conjunction with a fundal placenta), placenta accreta, maternal congenital abnormalities of the uterus, use of magnesium sulfate in the antepartum period, and primiparity.

**Clinical Features**

The patient will complain of sudden, severe abdominal pain. The abdominal examination reveals tenderness and an absence of the uterine corpus, which is potentially visualized at the cervical os or bulging from the introitus. Profuse bleeding with hemodynamic instability can also occur. Ultrasound may assist in the diagnosis.

**Management**

Once uterine inversion is identified, the appropriate mobilization of resources should begin simultaneously with efforts to
emergency clinicians can expect to encounter uterine rupture, identify a 30-minute window of opportunity that to speed delivery and repair the injury. ACOG guidelines for If uterine rupture is suspected, delivery should be hastened to ranges from nonreassuring fetal heart rate patterns to frank hemorrhagic shock. Prolonged fetal heart rate deceleration, indicating fetal distress, is the most reliable sign of fetal extrusion. Ultrasound may reveal a protruding amniotic sac, indicative of the sudden onset of hypoxia, coagulopathy or hemorrhage, seizure, fetal compromise, or cardiovascular collapse. DIC occurs in approximately 50% of cases, and maternal and feto mortality rates are high. Treatment is generally supportive and may include assisted ventilation, central hemodynamic monitoring, vasopressors, and the administration of blood products. Postpartum Endometritis Puerperal infections affect 5% of all vaginal deliveries and 10% of all cesarean sections. Operative delivery, prolonged rupture of membranes, lack of prenatal care, prolonged stage 2 labor, use of intrauterine monitoring, and frequent vaginal examinations have been linked to these ascending gynecologic infections. It is estimated that sepsis results in up to 15% of maternal deaths worldwide. Causative organisms for these infections include gram-positive cocci and gram-negative coliforms and, less commonly *Chlamydia* and *Mycoplasma* spp. Endometritis is the most common puerperal infection, usually developing on the second or third day postpartum. Typically, the lochia has a foul odor, and the white blood cell count is elevated. Fever and abdominal pain indicate greater severity of infection, often warranting inpatient care and intravenous antibiotics. A coexistent surgical wound infection is often present. A search for retained products of conception is indicated, particularly if bleeding is ongoing. Treatment is empirical and is directed at gram-positive, gram-negative, and anaerobic organisms. A combination of clindamycin and an aminoglycoside is recommended. Most patients with postpartum endometritis require admission. POSTPARTUM PROBLEMS Peripartum Cardiomyopathy For unclear reasons, the peripartum period is associated with the relatively sudden onset of cardiomyopathy in healthy women without evidence of prior cardiac disease. Estimates indicate that peripartum cardiomyopathy (PPCM) occurs in 1 of 2229 pregnancies; reported risk factors include advanced maternal age, preeclampsia, gestational hypertension, multiparity, and being African American. The cause is unknown. Onset usually occurs days to weeks after delivery; symptoms range from mild fatigue to florid pulmonary edema. PPCM is often unrecognized in its milder form, leading to the consensus that the condition may be more prevalent than reported. Dyspnea on exertion, orthopnea, and fatigue may be easily misinterpreted as normal in the postpartum period. The emergency clinician should not dismiss these symptoms because severe congestive heart failure, thromboembolism, and dysrhythmias may ensue. Treatment includes the use of diuretics, vasodilators, and oxygen. Angiotensin-converting enzyme inhibitors are contraindicated.
Postpartum Depression

Considered underdiagnosed, postpartum depression is estimated to affect 10% to 15% of new mothers. Although often self-limited, the condition has been recognized as having important consequences for the mother, infant, and family. Risk factors include previously diagnosed depression, inadequate spousal support, adverse socioeconomic factors, life stressors, and emergency delivery.

Clinical Features

Postpartum depression patients present similarly to those with other major depressive disorders. Symptoms include depressed mood, anhedonia, loss of appetite, insomnia, fatigue, decreased concentration, feelings of guilt and worthlessness, and suicidal ideation. Most women with postpartum depression do not have vegetative signs or symptoms. Symptoms peak at 10 to 12 weeks postpartum, although some cases are diagnosed up to 1 year after delivery. When postpartum depression is unrecognized, these women are at high risk for suicide and may come to the ED with overdoses or other manifestations of a suicidal attempt.

Management

Early identification and referral are the key components of therapy. Dismissal of postpartum fatigue as normal, without consideration of the diagnosis of postpartum depression, can be disastrous. Not only does this condition contribute to marital discord, maternal risk for suicide, and even infanticide, but studies have shown that children of depressed mothers have an increased incidence of delayed cognitive, psychological, neurologic, and motor development.

KEY CONCEPTS

- All ED deliveries should be considered high risk. Antepartum hemorrhage, PROM, eclampsia, premature labor, precipitous delivery, malpresentation, and umbilical cord emergencies are overrepresented in emergency deliveries.
- Women in labor who present to the ED are generally best cared for in the obstetric suite. Women with the urge to push or with the head of the infant crowning are at imminent risk of delivery, which should take place in the ED. The benefits of transfer of a woman with an impending high-risk delivery to a perinatal center must be carefully weighed against potential clinical adverse events and possible subsequent medicolegal judgments.
- Most ED deliveries require only basic equipment to cut and clamp the umbilical cord and dry and suction the infant. However, the ED should have additional equipment and trained staff available to care for a newborn requiring further resuscitation.
- Maternal complications of labor and delivery include obstetric trauma, postpartum hemorrhage, uterine inversion and rupture, amniotic fluid embolism, coagulation disorders, and infections. Many of these problems can initially be managed nonsurgically in the ED.
- Deliveries complicated by dystocia, malpresentation, or multiple gestations are life-threatening emergencies. The emergency clinician should develop strategies to treat each of these potential complications of delivery.

CHAPTER 181: QUESTIONS & ANSWERS

181.1. A 23-year-old G2P1 at term presents to the ED with contractions. She has received no prenatal care. She is in moderate distress and feels the urge to push. Which of the following is indicated?

A. Emergent delivery
B. Emergent transfer to the obstetrics suite
C. Formal abdominal ultrasound
D. Magnesium sulfate 2 g intravenously
E. Nitrazine testing of pooled vaginal fluid

Answer: A. Women with the urge to push or with the head of an infant crowning are at imminent risk of delivery, which should take place in the ED. Women in labor who present to the ED and are not at risk for imminent delivery are best cared for in the obstetrics suite.

181.2. A 28-year-old G3P3 presents 2 weeks after delivery with increasing dyspnea on exertion, pedal edema, orthopnea, and easy fatigue. Which of the following statements is true?

A. Angiotensin-converting enzyme (ACE) inhibitors are contraindicated.
B. Cardiac function returns to normal in 50% of cases.
C. Treatment differs from ischemic cardiomyopathy.
D. Onset is usually gradual.

Answer: B. Postpartum cardiomyopathy is associated with a fairly sudden onset of symptoms days to weeks after delivery. It may begin to occur during the end of pregnancy, at which time ACE inhibitors are contraindicated, but these agents are cornerstones of therapy after delivery. Fifty percent of patients will return to normal cardiac status. Mortality is high for those who do not.

181.3. Which of the following statements regarding uterine rupture is true?

A. Emergency ultrasonography has little value.
B. Emergent vaginal delivery is indicated.
C. Maternal mortality is high.
D. Pain is not always present.
E. The absence of vaginal bleeding precludes rupture.

Answer: D. Pain is not always present with uterine rupture, nor is vaginal bleeding always associated. Women at risk are those with a prior classic cesarean section incision or who have had three or more cesarean deliveries. Emergency ultrasonography may show a protruding amniotic sac, hemoperitoneum, or the site of myometrial rupture. Emergency cesarean delivery within 30 minutes is the indicated treatment. Maternal mortality rates in developed countries is less than 1%.

181.4. Which of the following statements is not associated with shoulder dystocia?

A. Fetal complications include clavicular fractures and hypoxic brain injury.
B. Shoulder dystocia can be overcome by placing traction on the fetal head.
C. Signs of shoulder dystocia include the turtle sign and the presentation of fetal shoulders in a vertical axis.
D. The McRoberts’ maneuver frees the anterior shoulder by flexing the mother’s legs to a knee-chest position.

Answer: B. Traction on the fetal head will extend and abduct the shoulders, which increases bisacromial diameter, thereby worsening the dystocia.

181.5. A 33-year-old G1P0 female at 38 weeks by dates presents to the ED with a chief complaint of “my water broke.” The patient reports feeling a gush of fluid several hours earlier but has not yet had any contractions. Which of the following statements best describes issues important in the evaluation and management of this patient?

A. Fetal tachycardia may be indicative of chorioamnionitis.
B. Nitrazine paper applied to the patient’s pooled vaginal fluid will confirm the presence of amniotic fluid by turning yellow.
C. Steroids should be given to the mother without delay to accelerate fetal lung maturation.
D. Tocolytics are indicated and should be administered if the patient develops contractions while in the ED.

Answer: A. This patient presents with premature rupture of membranes. Assuming that the fetal gestational age of 38 weeks is confirmed by ultrasound, steroids are unnecessary because fetal lung maturity has already taken place. The incidence of infection may be increased with steroid administration, so it should not be given in this case. Tocolytics are not clearly indicated in this patient because she is at term (ie, fetal lung maturity has taken place), and there is as yet no evidence of chorioamnionitis. Tocolytic use should be discussed with the obstetric consultant. Nitrazine paper should turn blue when it comes into contact with amniotic fluid.
fluid, indicating a pH over 6.5. Fetal tachycardia and decreased variability of fetal heart rate are both signs of chorioamnionitis.

181.6. Which of the following statements regarding fetal heart tracings is false?

A. Accelerations of heart rate occur during fetal movement.

B. Baseline heart rate is determined with a 10-minute tracing in the absence of contractions.

C. Late decelerations rarely result in suboptimal infant outcomes.

D. Persistent variable decelerations may indicate the need to hasten delivery.

Answer: C. Late decelerations indicate uteroplacental insufficiency and should prompt immediate obstetric consultation. Overall, 70% of infants with late decelerations have underlying pathologic conditions or hypoxia.
PRINCIPLES

Background

Trauma occurs in up to 8% of all pregnancies and is the leading non-obstetric cause of maternal death. The most common causes of injury in pregnancy are motor vehicle collisions (MVCs), interpersonal violence, and falls. The major determinant of obstetrical outcomes after trauma is the severity of the injury. Trauma in pregnancy increases the risk of spontaneous abortion, preterm rupture of membranes, preterm birth, uterine rupture, cesarean delivery, placental abruption, and stillbirth. A significant number of pregnant women admitted to a trauma center do not yet know that they are pregnant.

Commonly used thresholds of fetal viability are an estimated gestational age of 24 to 26 weeks or an estimated fetal weight of 500 g. Only viable fetuses are monitored, because no obstetric intervention will alter the outcome with a previable fetus. Counseling on proper seatbelt and alcohol use and screening for interpersonal violence may help to reduce the morbidity and mortality rates for pregnant patients. Although the essential principles of trauma management remain unchanged in the pregnant patient, a number of special points need to be considered because a gravid uterus does alter the pattern of injury. Pregnancy causes alterations in physiology and anatomy that affect multiple organ systems. Although there are two lives involved, maternal life takes priority and fetal outcomes are directly correlated with early and aggressive maternal resuscitation.

ANATOMY AND PHYSIOLOGY

Anatomic Changes in Pregnancy

The uterus remains an intrapelvic organ until approximately the 12th week of gestation. It reaches the umbilicus by 20 weeks and the costal margins by 34 to 36 weeks. At term, the uterus has often enlarged by 30 cm and has increased fifteen fold in weight, which alters the normal anatomic location and function of multiple structures. The diaphragm progressively rises in pregnancy with compensatory flaring of the ribs, which may predispose to pneumothorax and a faster progression to tension pneumothorax. A thoracostomy done in the third trimester requires that the chest tube be placed one or two interspaces higher than the usual fifth interspace site to allow for diaphragm elevation.

Abdominal viscera are pushed upward by the enlarging uterus and can alter the location of perceived pain. The gravid uterus itself tends to protect abdominal organs from trauma but substantially increases the likelihood of bowel injury from penetrating trauma to the upper abdomen. Conversely, the upward displacement of the bowel makes it less susceptible to blunt trauma.

Physiologic Changes

Cardiovascular

The normal cardiovascular changes of pregnancy can alter the clinical presentation and may either mimic or mask the recognition of shock or exacerbate the effects of traumatic hemorrhage (Table 182.1). Blood pressure declines in the first trimester, levels out in the second trimester, and then returns to nonpregnant levels during the third trimester. The decline in systole is small, 2 to 4 mm Hg, whereas diastole falls 5 to 15 mm Hg. Heart rate increases in pregnancy but does not rise by more than 10 to 15 beats per minute above baseline (mean of approximately 90 beats/min).

A major contributor to maternal hypotension is the supine hypotensive syndrome. After 20 weeks’ gestation, the enlarging uterus has risen to the level of the inferior vena cava, resulting in compression when the mother is supine. Caval obstruction diminishes cardiac preload, which can decrease cardiac output and systolic blood pressure. In late pregnancy, it is common for the inferior vena cava to become completely occluded when the pregnant patient is supine. Hemodynamic improvement occurs when compression is relieved. In determining whether observed hypotension is related to positioning, the pregnant woman’s pelvis can be tilted so that the uterus is displaced from the inferior vena cava (ie, tilt the patient onto her left side unless prevented by other injuries). The uterus can also be manually displaced to the left using two hands and pushing the uterus toward the patient’s head. Maintaining a position between 15 and 30 degrees is optimal. Elevating the patient’s legs will improve venous return. Inferior vena cava compression can also lower central venous pressure (CVP) in the last two trimesters. Normal CVP during pregnancy is approximately 12 mm Hg. Blood volume gradually increases during pregnancy, starting at 6 to 8 weeks’ gestation, to as much...
as 45% above normal, peaking at 32 to 34 weeks' gestation. Blood volumes become increasingly larger for multigravidas and for twin, triplet, and quadruplet gestations. With this increased circulatory reserve, clinical signs of maternal hypotension from acute traumatic bleeding may be delayed. Up to 35% of circulating blood volume may be lost before an injured pregnant patient exhibits signs or symptoms of shock. By the beginning of the second trimester and throughout the remainder of pregnancy, cardiac output is increased 40% to 6 L/min. Blood flow to the uterus increases from 60 mL/min before pregnancy to 600 mL/min at term. This hyperdynamic state is needed to maintain adequate oxygen delivery to the fetus. Because the mother's total circulating blood volume flows through the uterus every 8 to 11 minutes at term, this can be a major source of blood loss if injured. By the third trimester, there is also marked venous congestion in the pelvis and lower extremities, increasing the potential for hemorrhage from both bony and soft tissue pelvic injuries.

Compression of the lower abdominal venous system by the gravid uterus increases peripheral venous pressure and volume in the legs, creating the potential for brisk blood loss from leg wounds and can exacerbate bleeding from attempts at central venous catheter placement.

### Pulmonary

The pregnant woman at term has a significantly reduced oxygen reserve due to a reduction in functional residual capacity caused by diaphragm elevation and an increase in oxygen consumption related to the growing fetus, uterus, and placenta. Mean arterial oxygen tension drops by 29% in pregnant women at term during 60 seconds of apnea compared with 11% in nonpregnant women. Labor further accelerates this decline. In addition, minute ventilation and tidal volume increase, leading to hypocapnia. Therefore a partial pressure of carbon dioxide in the arterial blood (Paco₂) of 35 to 40 mm Hg may indicate inadequate ventilation and impending respiratory compensation in the pregnant patient. Maternal hypoxia rapidly leads to fetal hypoxia, distress, and possibly demise. There are no contraindications to rapid sequence intubation during pregnancy. Bag-valve-mask ventilation is more difficult in the pregnant patient. The incidence of difficult or failed intubations in obstetric anesthesia is four times higher than in surgical non-obstetric patients.

### Gastrointestinal

Gastroesophageal sphincter tone and gastrointestinal motility are decreased in pregnancy, thus increasing the possibility of aspiration in patients with altered level of consciousness, such as during intubation. Early gastric decompression should be performed in these circumstances.

### SPECIFIC DISORDERS

#### Blunt and Penetrating Trauma

Physical examination is unreliable in predicting adverse outcomes in the pregnant woman with blunt trauma. Risk factors predictive of the onset of contractions or preterm labor include gestational age greater than 35 weeks, assaults, and pedestrian collisions. In gravid patients, penetrating trauma of the abdomen increases the likelihood of injury to the bowel, liver, or spleen. Fetal mortality can be as high as 40% after maternal trauma, with most likely causes of fetal death occurring from placental abruption, maternal shock, and maternal death, in order of decreasing incidence. Risk factors significantly predictive of fetal death include ejection, motorcycle and pedestrian collisions, maternal death, maternal tachycardia, abnormal fetal heart rate, lack of restraints, and an injury severity score greater than 9.

Unbelted or improperly restrained pregnant women are twice as likely to experience excessive maternal bleeding and increased maternal death with fetal death being three times more likely to occur. For low- to moderate-severity crashes (constituting 95% of all MVCs), proper restraint use, with or without air bag deployment, generally leads to acceptable fetal outcomes. For high-severity crashes, even proper restraint does not improve fetal outcome.

Pregnant crash-test-dummy trials show that improper placement of the lap belt over the pregnant abdomen causes a threefold to fourfold increase in force transmission through the uterus. The lowest force transmission readings through the uterus occur when a three-point seat belt is used properly. For correct position, the lap belt should be placed under the gravid abdomen, snugly over the thighs, with the shoulder harness off to the side of the uterus, between the breasts and over the midline of the clavicle. Women
who receive information on seat belt use during pregnancy from a health care worker are statistically more likely to use seat belts and to use them properly than uninformed controls.

**Interpersonal Violence**

Physical abuse from husbands or boyfriends compromises a woman's health during pregnancy, as well as her likelihood of carrying a child to term and the health of her newborn. Women experiencing abuse in the year before or during a pregnancy were 40% to 60% more likely than non-abused women to report high blood pressure; vaginal bleeding; severe nausea; kidney or urinary tract infections; and hospitalization during that pregnancy. Abused pregnant women are more likely to deliver preterm, and children of abused pregnant women are more likely to be born underweight. Children born to abused mothers are more likely than other children to require intensive care at birth. Physicians detect only a minority of interpersonal violence cases in pregnant women, which supports the need for routine screening for interpersonal violence in this population.

**Falls**

Falls become more prevalent after the 20th week of pregnancy and at least one in four pregnant women will fall at least once while pregnant. Protuberance of the abdomen, loosening of pelvic ligaments, strain on the lower back, and fatigueability are contributory factors. In a given pregnancy, about 2% of pregnant women sustain repeated direct blows to the abdomen from repetitive falls. Although repeated falls often trigger premature contractions, they seldom result in immediate labor and delivery.

**Penetrating Trauma**

The gravid uterus affects the injury pattern seen with penetrating trauma to the upper abdomen with the probability of harm to the bowel, liver, or spleen at almost 100%. When the entry site is anterior and below the uterine fundus, visceral injuries are less likely. Although the enlarging uterus can act as a shield against intra-abdominal injuries in the mother, it makes the fetus more susceptible to injury. A high fetal death rate from penetrating trauma to the uterus has been reported and is lower for maternal injuries above the uterus.

**Fetal Injury**

There is a high risk of fetal loss in the pregnant trauma patient. Poor fetal outcome is predicted by maternal hypotension and acidosis (hypoxia, lowered pH, lowered bicarbonate) and a fetal heart rate of less than 110 beats/min. When the mother sustains life-threatening injuries, there is a 40% chance of fetal demise, compared with a less than 2% chance in cases of non-life-threatening maternal injuries. Disseminated intravascular coagulation (DIC), which may be caused by placental products entering the maternal circulation, is a significant predictor of fetal mortality. The American College of Obstetrics and Gynecology recommends a minimum of 2 to 6 hours of fetal monitoring after maternal trauma; cardiotocographic monitoring for a minimum of 4 hours is useful in predicting fetal outcome.

Fetal fetal injuries from blunt trauma are usually the result of intracranial hemorrhage and skull fractures secondary to fractured maternal pelvic bones striking the fetal skull as a result of vertex lie. Pelvic and acetabular fractures during pregnancy are associated with a high maternal (9%) and a higher fetal (38%) mortality rate. Both gunshot wounds and stab wounds to the uterus produce substantial morbidity and mortality to the fetus.

**Placental Injury**

The leading cause of fetal death after blunt trauma is placental abruption. Placental separation results when the inelastic placenta shears away from the elastic uterus during sudden deformation of the uterus. Because deceleration forces can be as damaging to the placenta as direct uterine trauma, abruption can occur with little or no external sign of injury to the abdominal wall. Placental abruption inhibits the flow of oxygen to the fetus and causes in utero carbon dioxide (CO₂) accumulation, resulting in hypoxia and acidosis and leads to fetal distress. Sustained uterine contractions induced by intrauterine hemorrhage also inhibit uterine blood flow, further contributing to fetal hypoxia.

The diagnosis of abruption is made on clinical grounds; ultrasonography and the Kleihauer-Betke test are of limited value. Classic clinical findings of abruption are vaginal bleeding, abdominal cramps, uterine tenderness, maternal hypovolemia (up to 2 L of blood can accumulate in the gravid uterus), or a change in the fetal heart rate; but many cases of placental abruption after trauma present without vaginal bleeding.

The most sensitive indicator of placental abruption is fetal distress, which can be detected with prompt fetal monitoring. Increased frequency of contractions is associated with abruption. Ultrasonography has poor sensitivity for detection of placental abruption (24% sensitivity; 96% specificity). If the abruption bleeds externally, there may be an insufficient quantity to be detected sonographically. Even with significant intrauterine blood accumulation, accurate ultrasonography diagnosis may be difficult because of placental position (ie, posterior) and confounding uterine or placental structural conditions.

Placental abruption is associated with an increased risk of stillbirth (>20 weeks) and preterm delivery (before 37 weeks) even with minor abruption. The extent of placental separation is correlated with the rate of stillbirth.

A trial of expectant management with ongoing maternal and fetal monitoring is appropriate when mother and fetus are stable and with partial placental abruptions of less than 25%. This usually applies to fetuses of less than 32 weeks’ gestation in which the likelihood of morbidity and mortality associated with prematurity makes delivery management risky. Expectant care in stable patients may allow further fetal maturation and improved outcome. An immediate cesarean section should be available in case of fetal distress from further placental separation. After 32 weeks’ gestation, the risk of further placental separation outweighs the benefits of further fetal maturation, so intervention is indicated.

Women with placental abruption are more likely to have coagulopathies than those without abruption. The injured placenta can release thromboplastin into the maternal circulation, resulting in DIC, whereas the damaged uterus can disperse plasminogen activator and trigger fibrinolysis. The precipitation of DIC is directly related to the degree of placental separation. Severe clotting disorders rarely occur unless separation of the placenta is significant enough to result in fetal demise.

**Uterine Injury**

The most common obstetric problem caused by maternal trauma is uterine contractions. Myometrial and decidual cells, irritated by contusion or placental separation, release prostaglandins that stimulate uterine contractions. Progression to labor depends on the extent of uterine damage, the amount of prostaglandins released, and the gestational age of the pregnancy. The routine use of tocolytics for premature labor has come under question because most contractions stop spontaneously. Contractions that are not self-limited are often induced by some pathologic condition, such as underlying placental abruption, which is a contraindication to
tocolytic therapy. Older studies describe this risk as relative and have used tocolysis successfully with careful evaluation and intensive monitoring to continue the pregnancy and enhance fetal maturity. The option to use tocolytics ends when cervical dilation reaches 4 cm.

Uterine rupture is a rare event. It is most often caused by severe vehicular crashes in which pelvic fractures strike directly against the uterus. Uterine rupture may occur from stab wounds and gunshot injuries, but this is rare. Maternal shock, abdominal pain, easily palpable fetal anatomy caused by extrusion into the abdomen, and fetal demise are typical findings on examination. Diagnosing uterine rupture can be difficult. A fractured liver or spleen can produce similar signs and symptoms of peritoneal irritation, hemoperitoneum, and unstable vital signs. Optimal treatment, between suturing the tear or performing a hysterectomy, depends on the extent of uterus and uterine vessel tears and the importance of future childbearing.

DIAGNOSTIC TESTING

All women of childbearing age presenting with trauma should be assessed for possible pregnancy.

CHANGES IN LABORATORY VALUES WITH PREGNANCY

Increases in plasma volume and red blood cells cause physiologic anemia of pregnancy (hematocrit 32% to 34% by the 32nd to 34th week). Despite the lower hematocrit, there is an overall increase in oxygen-carrying capacity because of an increased total red blood cell mass. Placental progesterone directly stimulates the medullary respiratory center, producing a lower PaCO₂ (30 mm Hg) from the second trimester until term. The subsequent compensatory lowering of serum bicarbonate slightly reduces blood-buffering capacity during conditions of physiologic stress. A PaCO₂ of 40 mm Hg in the latter half of pregnancy reflects inadequate ventilation and potential respiratory acidosis that could precipitate fetal distress.

Electrocardiographic changes include a left-axis shift averaging 15 degrees, caused by diaphragm elevation. Consequently, flattened T waves or Q waves in leads III and augmented voltage unipolar left limb lead may be seen.

Laboratory

Laboratory tests for a pregnant patient with trauma should include a blood type with Rh status, arterial blood gas, and coagulation studies. Patients who appear to be stable but have a low serum bicarbonate level may have occult maternal shock. Interpretation of bicarbonate results requires consideration of the physiologic changes that occur in the later stages of pregnancy as a result of respiratory alkalosis. Coagulation studies are important in directing management of patients with multisystem trauma or when the diagnosis of placental abruption is considered.

Kleihauer-Betke Test and Fetomaternal Hemorrhage

Fetomaternal hemorrhage (FMH), the transplacental bleeding of fetal blood into the normally separate maternal circulation, is a unique complication of pregnancy. MVCs, anterior placental location, and uterine tenderness are associated with an increased risk of FMH. Massive fetomaternal transplacental hemorrhage causes alloimmunization in Rh incompatibility but also endangers the fetus by causing severe fetal anemia, fetal distress, and possible exsanguination. ABO incompatibility causes less severe disease.

In theory, it is possible that trauma can result in FMH as early as the fourth week of gestation, when the fetal and placental circulations first form. In practice, FMH is usually of more concern after 12 weeks’ gestation, when the uterus rises above the pelvis and becomes susceptible to direct trauma.

The Kleihauer-Betke test quantifies the amount of FMH. Most laboratories screen for FMH of 5 mL or more, even though the amount of FMH sufficient to sensitize most Rh-negative women is well below this 5-mL sensitivity level. Therefore it is advisable that all Rh-negative mothers who have a history of abdominal trauma receive one prophylactic dose of Rhesus immune globulin (RhIG) within 72 hours of injury. Trauma patients at risk for massive FMH will have major injuries or abnormal obstetric findings, such as uterine tenderness, contractions, or vaginal bleeding. Rarely, the amount of FMH will exceed that covered by the maximum RhIG dose (300 µg). Because RhIG can effectively prevent Rh isoimmunization when administered as late as 72 hours after antigenic exposure, the results of the Kleihauer-Betke test are not immediately needed in the emergency department (ED).

Radiography

Plain Radiographs

Adverse effects to the fetus are unlikely if radiation exposure is less than 50 mGy. Less than 1% of trauma patients are exposed to more than 30 mGy. Sensitivity to radiation is greatest during intrauterine development when the embryo undergoes organogenesis in weeks 2 to 15. However, the risk to the fetus of a 10 mGy exposure is thousands of times smaller than the spontaneous risks of malformations, abortions, or genetic disease. Intrauterine exposure to 50 mGy does not appear to cause a significant increase in congenital malformations, intrauterine growth retardation, or miscarriage but is associated with a 2% increase in the risk of cancer. Pathologic conditions more readily appear with intrauterine radiation doses of 150 mGy or greater (at this point, a therapeutic abortion may be considered).

Providing information on radiation exposure from diagnostic radiographs is difficult. Fetal dose from computed tomography (CT) scans depends on many factors, but the type of equipment used, the abdominal girth of the mother, and the fetal distance from the maternal skin are important factors. Diagnostic radiographic studies should be performed with regard for fetal protection, but necessary diagnostic studies of the traumatized pregnant patient should not be withheld out of concern for fetal radiation exposure. When appropriate, fetal irradiation should be minimized by limiting the scope of the examination and using technical means, such as shielding and collimation. Table 182.2 provides estimated radiation doses from various types of examinations.

Ultrasonography

Ultrasonography is the best modality for simultaneous assessment of both the mother and the fetus. In the pregnant patient, it is most useful in detecting major abdominal injury, establishing fetal well-being or demise, gestational age, and placental location. However, ultrasonography has low sensitivity (24%) but high specificity (96%) for placental abruption. Ultrasonography can obviate more hazardous tests, such as CT, cystography, and diagnostic peritoneal lavage (DPL) when a pregnant trauma patient requires an objective evaluation of the abdomen. Limitations in accuracy include operator experience, patient obesity, the presence of subcutaneous air, and a history of multiple abdominal surgeries. If ultrasound findings are equivocal and the patient is hemodynamically unstable, DPL performed in an open
Radiation from CT is a concern in the pregnant trauma patient. Radiographics 34(3):748–763, 2014.

and supra-uterine fashion is indicated. Diagnostic peritoneal aspiration (DPA) may be considered in conjunction with a trauma surgeon; however, this procedure also poses risks.

Computed Tomography and Magnetic Resonance Imaging Scans

CT and, increasingly, magnetic resonance imaging (MRI) studies are used in evaluating abdominal trauma in pregnancy. If ultrasonography is indeterminate and the patient’s condition is stable, CT and MRI can identify specific organ damage. They are particularly useful in assessing penetrating wounds of the flank and back. CT can miss diaphragm and bowel injuries. Both of these studies carry the risk of moving the patient from the closely monitored environment of the ED to a distant radiography suite.

Radiation from CT is a concern in the pregnant trauma patient. However, with shielding, fetal exposure from head and chest CT scans can be kept below an acceptable 1-rad limit. CT of the abdomen can be done with 4 mGy of exposure to the fetus. CT of the abdomen and pelvic CT produces about 25 mGy of radiation to the fetus, which is well below the 50 mGy level, where a 2% increase in risk of cancer is seen without evidence of malformation to the fetus. Radiation exposure ultimately depends on the patient, scanner, and technique used in performing the study (see Table 182.2). MRI scanners use no radiation and have not been associated with significant fetal disease or disability.

**SPECIAL PROCEDURES**

**Diagnostic Peritoneal Lavage**

In unstable trauma patients with equivocal or negative findings on ultrasonography, DPL can be done in any trimester by an open technique above the uterus after placement of a nasogastric tube and a Foley catheter. The gravid uterus, in the later trimesters, makes the procedure more risky and technically challenging. In blunt trauma, the gravid uterus does not compartmentalize intraperitoneal hemorrhage and does not reduce the accuracy of DPL for identifying patients who need operative intervention for intra-abdominal bleeding. DPL is limited in detecting bowel perforations and does not assess retroperitoneal and intraperitoneal pathology.

**MANAGEMENT**

Depending on mechanism, maternal condition, and gestational age, the emergency clinician should consider early notification or consultation with an obstetrician, neonatologist, or pediatrician (or all three). A fetal monitor, portable ultrasound, and neonatal resuscitation equipment should be immediately available. Tetanus toxoid and immune globulin have no detrimental effect on the fetus. The World Health Organization (WHO) specifically recommends vaccination during pregnancy. To prevent alloimmunization of an Rh-negative mother, administer one 50-µg dose of RhIG in the first trimester. It is sufficient because total fetal blood volume is only 4.2 mL by 12 weeks’ gestation, and a 50-µg dose covers 5 mL of bleeding. During the second and third trimesters, a 300-µg dose of RhIG is given, which protects against 30 mL of FMH. Beyond 16 weeks’ gestation, the total fetal blood volume reaches 30 mL or more. Massive FMH likely exceeds the efficacy of one 300-µg dose of RhIG, so the Kleihauer-Betke test can be used to guide effective dosing.

**Maternal Resuscitation**

**Primary Survey**

The primary survey focuses on the mother. However, because two patients are present, it is reasonable also to gather preliminary information about the fetus at this time (Fig. 182.1).

**Airway and Breathing**

Oxygen therapy should be instituted early. Because of reduced oxygen reserve and increased oxygen consumption, the traumatized pregnant woman can quickly become hypoxic. The fetus is very vulnerable to any reduction in oxygen delivery. Supplemental oxygen should be continued throughout maternal resuscitation and evaluation. A secure airway enables proper oxygenation and negates the higher risk of aspiration in pregnancy. Rapid sequence intubation is recommended. Pre-oxygenation of the pregnant patient is described in Chapter 1. Mechanical ventilation settings need to be adjusted for increased tidal volumes and respiratory alkalosis, which is consistent with the physiologic PaCO₂ of 30 mm Hg in the last stage of pregnancy.

**Circulation**

Intravenous access above the diaphragm is preferred. Maternal blood pressure and heart rate are not consistently reliable predictors of fetal and maternal hemodynamic stability. Due to an expanded circulating volume, the mother can hemorrhage but not show early signs of hypotension. Uterine blood flow is markedly reduced when maternal circulation is compromised. As a result, after an acute blood loss, uterine blood flow can be substantially decreased while maternal blood
pressure remains normal. Consequently, the pregnant woman with borderline hemodynamic stability probably already has a jeopardized fetus. When traditional signs of shock appear, fetal compromise may be far advanced. Vasopressors should be avoided, because they produce fetal distress by further decreasing uterine blood flow.

Beyond 20 weeks’ gestation, tilting the patient to approximately 30 degrees to the left on a backboard or elevating the right hip reduces the compression on the inferior vena cava caused by the gravid uterus. Tilting to the right is less effective in removing the uterus from the inferior vena cava; manually displacing the uterus upward and leftward is more effective.

For severe injuries, a CVP line is helpful in assessing cardiac preload. CVP pressures decline as pregnancy progresses because of inferior vena cava compression by the gravid uterus. Therefore correction to nonpregnant normal pressures may be unnecessary. Instead, it is more valuable to focus on trends of how the CVP responds to fluid resuscitation. A Foley catheter for measuring urine output provides further information on circulatory volume status.

With trauma in pregnancy, the primary survey is modified to assess uterine size and the presence of fetal heart tones if the patient is severely injured. Otherwise, this assessment belongs in the secondary survey. Uterine size, measured from the symphysis pubis to the fundus, is the quickest means of estimating gestational age. This distance in centimeters equals the gestational age in weeks (eg, 24 cm = 24 weeks), which allows some early indication of fetal viability if delivery is necessary (Fig. 182.2). Usually, 24 to 26 weeks is used as the cutoff point for fetal viability (Table 182.3). As a rough guide, the fetus is potentially viable when the dome of the uterus extends beyond the umbilicus. Fetal heart tones can be detected by auscultation at 20 weeks’ gestation or by Doppler probe at 10 to 14 weeks. If either the uterus is less than 24 cm in size or fetal heart tones are absent, the pregnancy is probably too early to be viable, and treatment is directed solely at the mother.

### Secondary Survey

The secondary survey involves a detailed examination of the patient but is also modified to gather additional information about the maternal abdomen and the fetus. Physical examination of the abdomen, frequently unreliable in the nonpregnant patient, is even more inaccurate with changing organ position, abdominal wall stretching in advancing pregnancy, and uterine contraction pains. Still, valuable information can be gathered about uterine tenderness, contraction frequency, and vaginal bleeding.

Pelvic examination begins with sterile speculum examination to allow direct visualization to enable detection of possible trauma in the genital tract, the degree of cervical dilation, and the source of any observed vaginal fluid. Vaginal bleeding suggests placental abruption, and a watery discharge suggests rupture of the membranes. If a vaginal fluid sample placed on a slide dries and crystallizes in a ferning pattern, it is amniotic fluid and not urine. Cervical cultures for group B streptococci, Neisseria gonorrhoeae, and Chlamydia should be performed if there is evidence of amniotic fluid leak. Bimanual examination should be limited to assessing for pelvic bone injury or progression of advanced labor. If the mechanism of injury is significant enough and the fetus is judged...
to be viable, early involvement of an obstetrician may enhance the fetal outcome.

**Fetal Evaluation.** Fetal evaluation in the secondary survey focuses on the fetal heart rate and detection of fetal movement. When the presence of fetal heart tones has been confirmed, intermittent monitoring of fetal heart rate is sufficient for the previable fetus. If the fetus is viable (ie, 24 weeks or more), continuous external monitoring initiated quickly and maintained throughout all diagnostic and therapeutic procedures may be useful in directing management. Such monitoring can also benefit the mother, because fetal hemodynamics are more sensitive to decreases in maternal blood flow and oxygenation than are most measures of the mother. Fetal distress can be a sign of occult maternal distress. However, fetal distress and even demise can occur with seemingly minor maternal trauma. Signs of fetal distress include an abnormal baseline heart rate, decreased variability of heart rate, and fetal decelerations after contractions.

The normal fetal heart rate ranges from 120 to 160 beats/min; rates outside or trending toward these limits are ominous. Heart rate variability has two components. Beat-to-beat variability measures autonomic nervous function, whereas long-term variability indicates fetal activity. Heart rate variability increases with gestational age. The loss of beat-to-beat and long-term variability warns of fetal central nervous system depression and reduced fetal movement caused by fetal distress (Fig. 182.3).

Late decelerations are an indication of fetal hypoxia. These decelerations are relatively small in amplitude and occur after the peak or conclusion of a uterine contraction. By comparison, early decelerations are larger, occur with the contraction, and recover to baseline immediately after the contraction. Early decelerations may be vagally mediated when uterine contractions squeeze the fetal head, stretch the neck, or compress the umbilical cord. Variable decelerations are large, occur at any time, and are possibly caused by umbilical cord compression (Fig. 182.4).

**Mother Stable, Fetus Stable**

Minor trauma does not necessarily exempt the fetus from significant injury. It is estimated that up to 3% of all minor trauma results in fetal loss, typically from placental abruption. Therefore, once the traumatized mother is stabilized, the focus of care is directed toward the fetus. For the viable fetus (greater than 24 weeks’ gestation), monitoring is the next step. Continuous monitoring maintained throughout all diagnostic and therapeutic actions is advisable. Because direct impact is not necessary for fetoplacental pathology to occur, the traumatized pregnant woman with no obvious abdominal injury still benefits from monitoring.

The recommended 4 hours of cardiotocographic observation of the viable fetus is extended to 24 hours if at any time during the first 4 hours there are more than three uterine contractions per hour, uterine tenderness persists, results on a fetal monitor strip are worrisome, vaginal bleeding occurs, the membranes rupture, or any serious maternal injury is present. Most cases of placental abruption after maternal trauma are detected within the first 4 hours of monitoring.

On discharge from the hospital, the pregnant woman should be instructed to record fetal movements during the next week. If fewer than four movements per monitored hour are noted, the patient should see her obstetrician immediately and a nonstress test is warranted. The occurrence of preterm labor, membrane rupture, vaginal bleeding, or uterine pain also necessitates prompt reevaluation. Serial ultrasound and fetal heart rate tests on viable fetuses a few days after maternal trauma and periodically throughout the remaining portion of the pregnancy are helpful in monitoring fetal well-being.

**Mother Stable, Fetus Unstable**

Fetal death rates after maternal trauma are three to nine times higher than maternal death rates. If a viable fetus remains in distress despite optimization of maternal physiology, cesarean section should be considered.

Although fetal viability is first reached at 24 weeks, the ultimate determinant of the age of fetal viability is the level of neonatal care provided by the intensive care nursery unit in each hospital or accessible regional facility. Determining gestational age for fetuses of less than 29 weeks may be difficult. Emergency decisions on fetal viability are therefore made on the basis of the best ultrasonography and gestational age information available.

---

**Fig. 182.3.** Types of fetal heart rate variability. bpm, Beats per minute; FHR, fetal heart rate; UA, uterine activity.
The presence of fetal heart tones is an important survival marker for fetuses about to undergo emergency cesarean section. The fetal survival rate is zero if there are no fetal heart tones present when emergency cesarean section commences. If fetal heart tones are present and the gestational age is 26 weeks or more, then infant survival rate may be as high as 75%.

Besides fetal distress, other reasons for a cesarean section include uterine rupture, placental rupture with significant vaginal bleeding, fetal malpresentation during premature labor, and situations in which the uterus mechanically limits maternal repair. Fetal demise without any of the aforementioned conditions is not an indication for cesarean section, because most will pass spontaneously within 1 week.

**Mother Unstable, Fetus Unstable**

If the mother’s condition is critical, primary repair of her wounds is the best course. This may apply even when the fetus is in distress, because an acutely ill mother may not be able to withstand an additional operative procedure such as cesarean section, which prolongs laparotomy time and likely substantially increases blood loss. The best initial action on behalf of the fetus is early and aggressive restoration of normal maternal physiology. If it is felt that the unstable mother can tolerate an emergency cesarean section, it should be considered for the distressed, viable fetus.

As with nonpregnant patients, operative intervention for blunt trauma and above-the-uterus stab wounds is dictated by clinical findings and diagnostic testing results. Above-the-uterus intra-peritoneal gunshot wounds require exploration. In situations of severe maternal hemorrhage, massive transfusion protocols should be initiated with fresh frozen plasma, platelets, and red blood cells in a 1 : 1 : 1 ratio to lower the rate of coagulopathy and improve survival. There is little evidence to support a definitive management strategy for penetrating trauma to the gravid uterus. In situations of a hemodynamically stable mother, expectant management has been recommended. However, no prospective study has verified this. Damage to the uterus alone can be quite devastating because of its increased circulation. Without exploration, it is impossible to know the occurrence, size, or depth of uterine penetration, and there are no guidelines indicating whether a uterine wound can be left unsutured without incurring an increased risk of infection or delayed uterine rupture. Laparotomy or laparoscopy seems to be the safest means of managing penetrating uterine wounds, because missed maternal injuries can quickly compromise the fragile fetus.

**Defibrillation**

Electrical flow that bypasses the fetus has little effect on the pregnancy. Maternal elective and emergent cardioversion has been performed safely for cardiac dysrhythmias in all three stages of pregnancy. Energies up to 300 Joules have been used without affecting the fetus or inducing premature labor. Although the amount of energy reaching the fetal heart is thought to be small, it is advisable to monitor the fetal heart during maternal cardioversion.

**Perimortem Cesarean Section**

Restoration of maternal and thus fetal circulation is the optimal goal with maternal hemodynamic instability. However, extended and exclusive attention to the mother in cardiopulmonary arrest may prevent recovery of a potentially viable fetus. During maternal resuscitation, adequate oxygenation, fluid loading, and a 30-degree left tilting position or manual displacement of the gravid uterus, may improve maternal circulation. If there is no response to advanced cardiac life support, a decision for perimortem cesarean section, also referred to as resuscitative hysterotomy, should be made within 4 minutes. Perimortem cesarean section in the ED should be considered only if uterine size exceeds the umbilicus. Time since maternal circulation ceased is the critical factor in fetal outcome. Delivery increases venous return and cardiac output by 25% to 30% and may lead to survival benefit for mother. Published reports support but fall short of proving that perimortem cesarean delivery should be initiated within 4 minutes of the onset of maternal cardiac arrest and no return of spontaneous circulation. Beyond 20 minutes, there is virtually never survival or favorable neurologic outcome for either mother or fetus.
In the event of maternal cardiopulmonary arrest, perimortem cesarean section should be performed. The most experienced physician available should perform the procedure as cardiopulmonary resuscitation (CPR) is continuing. A midline vertical incision is made from the epigastrium to the symphysis pubis. The uterus is then entered with a midline vertical incision. If necessary, the placenta is incised to reach the fetus; once the fetus has been delivered, the cord is clamped and cut. Maternal revival after delivery of the fetus has been reported in a few perimortem circumstances, presumably because vena caval compression is relieved.

**KEY CONCEPTS**

- Management of life- and limb-threatening injury in the mother comes first. Saving the mother provides the best chance of saving the baby.
- Even in the stable pregnant trauma patient, the fetus is at increased risk of morbidity and mortality.
- The fetus is viable at 24 weeks’ gestation. This usually corresponds to when the fundus is at or above the umbilicus.
- Alterations in anatomy and physiology that occur during pregnancy may alter clinical findings related to blood loss and may mask injuries, making methodical assessment essential.
- Stable pregnancies with a viable fetus should be monitored continuously for a minimum of 4 hours after trauma.
- Keeping the mother tilted 30 degrees to the left or manually displacing the uterus may alleviate hypotension and improve perfusion for the mother and fetus.
- Perimortem cesarean section should be initiated for a viable fetus within 4 minutes of no spontaneous return of circulation.
- The use of ionizing radiation to the pregnant patient, including CT and plain radiography, should be minimized, but imaging should not be withheld if it may provide significant diagnostic information. Often, ultrasound, MRI, or a period of observation can preclude the need for ionizing radiation.

**DISPOSITION**

Any pregnant woman at 24 or more weeks of gestation who has sustained blunt trauma should undergo at least 4 hours of fetal monitoring even if she looks well. In general, pregnant women who sustain minor trauma have a favorable pregnancy outcome. Other admission and operative criteria are similar for pregnant and nonpregnant trauma patients. The emergency clinician should consider the stability of the mother and the viability of the growing fetus when making management and disposition decisions.

CHAPTER 182: QUESTIONS & ANSWERS

182.1. In cases involving minor trauma to pregnant women, which of the following is a predictor of fetal outcome?

A. Abdominal tenderness
B. Cardiotocographic monitoring for 4 hours
C. Maternal blood count and arterial blood gas results
D. Maternal vital signs
E. Ultrasonography

Answer: B. For women with mild trauma, fetal outcome is not predicted by maternal vital signs, abdominal tenderness, blood tests, or ultrasound results. Only cardiotocographic monitoring for a minimum of 4 hours is useful to predict fetal outcome.

182.2. Which of the following factors is most concerning in the presentation of a pregnant trauma patient?

A. Diastasis of the symphysis pubis
B. Electrocardiogram (ECG) findings of Q waves in III and aVF
C. Hematocrit 34% in third trimester
D. Hypotension in the third trimester
E. Respiratory alkalosis in the third trimester

Answer: D. Blood pressure declines in the first trimester, levels out in the second trimester, and then returns to nonpregnant levels during the third trimester. In pregnancy, minute ventilation increases, leading to hypopcapnia. Therefore a partial pressure of arterial carbon dioxide (Paco₂) of 35 to 40 mm Hg may indicate inadequate ventilation and impending respiratory decompensation. The physiologic anemia of pregnancy, resulting from a 48% to 58% increase in plasma volume and only an 18% increase in red blood cells, results in hematocrits of 32% to 34% by gestational age of 32 to 34 weeks. Electrocardiographic changes include a left-axis shift averaging 15 degrees, caused by diaphragm elevation. Consequently, flattened T waves or Q waves in leads III and aVF may be seen.

182.3. A 26-week gravid woman presents to the emergency department (ED) after a moderate-speed motor vehicle collision (MVC). The patient is without complaints, and her vital signs are as follows: blood pressure, 100/60 mm Hg; heart rate, 100 beats per minute; and respiratory rate, 18 breaths per minute. Ultrasound examination shows good fetal movement, with a fetal heart rate of 150 beats per minute. What is the appropriate disposition for this patient?

A. Consult obstetrics for a minimum of 4 hours of cardiotocographic monitoring.
B. Consult obstetrics for 1 hour of cardiotocographic monitoring.
C. Consult trauma and obstetrics for admission and serial examinations.
D. Consult trauma and obstetrics for clearance to discharge patient.
E. Discharge the patient with close follow-up with obstetrics.

Answer: A. Placental abruption results when the inelastic placenta shears away from the elastic uterus during sudden deformation of the uterus. Because deceleration forces can be as damaging to the placenta as direct uterine trauma, abruption can occur with little or no external sign of injury to the abdominal wall. For the viable fetus (more than 24 weeks’ gestation), monitoring is the next step.

182.4. A 33-year-old pregnant patient complains of abdominal cramping after a trip and fall accident at home. After 4 hours of cardiotocographic monitoring, the patient was admitted to the obstetric service for further evaluation. What was the least likely reason for the admission?

A. Late decelerations on fetal monitoring strip
B. Leakage of clear fluid from the os
C. Maternal pulmonary contusion
D. Persistent uterine tenderness
E. Two uterine contractions per hour

Answer: E. The recommended 4 hours of cardiotocographic observation of the viable fetus should be extended to 24 hours if at any time during the first 4 hours there are more than three uterine contractions per hour, persistent uterine tenderness, a worrisome fetal monitor strip, vaginal bleeding, rupture of the membranes, or if any serious maternal injury is present.
182.5. A 26-year-old, 30-week gestation woman presents unresponsive with cardiopulmonary resuscitation (CPR) in progress after a high-speed motor vehicle collision (MVC). On ultrasonography, the fetal heart beat is noted at a rate of 130 beats per minute. The patient lost her vital signs 3 minutes before arrival in the emergency department (ED). What is the most appropriate next step in the management of this patient?

A. Perimortem cesarean section in the operating room by obstetrics
B. Perimortem cesarean section with horizontal suprapubic incision
C. Perimortem cesarean section with vertical incision
D. Thoracotomy with cardiac massage
E. Thoracotomy with cross-clamping of the aorta

Answer: C. In the event of maternal cardiopulmonary arrest, perimortem cesarean section is indicated. The most experienced physician available should perform the procedure.
CHAPTER 183

Approach to the Geriatric Patient

Jennifer C. Chen

PRINCIPLES

Epidemiology and Demographics

The current growth in the population of older adults is unprecedented in the history of the world, driven by longer life expectancies in developed countries. In the United States, the additional demographic contribution of the aging of the large baby boomer generation (about 10,000 boomers will turn 65 years old every day for the next 15 years) makes those aged 65 years and older the fastest growing segment of the US population (Fig. 183.1). From 2010 to 2050, the population of US older adults will more than double, and those aged 85 years and older will more than triple.

Causes of death in adults older than 65 years have shifted from infectious diseases and acute illnesses to chronic diseases as the leading causes of death in older Americans, with associated declines in functional status, cognition, and social supports. These demographic changes—the increasing burden of chronic diseases, and financial, transportation, and functional limitations unique to older adults—translate into older people presenting to emergency departments (EDs) in greater numbers and at higher rates than any other age groups. Older patients have the greatest degree of resource use, longest length of stay, and highest admission rates of any age group. Older adults are also at high risk of adverse health outcomes after an ED visit; within the first 3 months after ED discharge, approximately 5% of older people will die, 20% will be hospitalized, and 20% will have a return outpatient ED visit.

Assessing the Older Patient

Obtaining a detailed history remains a mainstay of clinical care in older adults. However, older patients more often have cognitive, functional, and sensory impairments or depression that limit their ability to communicate. These syndromes, associated with aging and complications of the ED and may be underappreciated and underrecognized by emergency clinicians. History taking may need to expand beyond just asking the patient to include caregivers and institutions such as nursing home. Patients and caregivers may have difficulties recalling all the details of a long and complex history or multiple medications; therefore, careful review of medical records and medication lists are important adjuncts to the history.

Routine performance of a cognitive assessment in older patients has been identified as a geriatric quality indicator for EDs. Patients with cognitive dysfunction, which includes mild cognitive impairment, dementia, and delirium, are less able to comprehend discharge instructions. Early performance of cognitive assessment in the evaluation of the older patient can improve quality of care and disposition planning.

Delirium, an acute confusional state with alterations in cognition and attention, occurs in around 10% to 20% of older ED patients. Unfortunately, emergency clinicians miss recognizing delirium up to 75% of the time, especially with the hypoactive subtypes of delirium. There are several brief assessment tools available, including the Confusion Assessment Method (CAM; Fig. 183.2). Delirium is generally caused by decreased neurologic reserve plus one or more acute precipitants, such as infection, metabolic abnormalities, and acute coronary syndromes. Delirium and dementia are sometimes difficult to distinguish from one another, but the distinction is important because the presence of delirium should lead to concern for a potentially life-threatening medical emergency. Older ED patients with delirium have higher intensive care unit (ICU) admission, 30-day mortality and 30-day readmission rates.

Studies that have universally screened older ED patients found rates of dementia of about 35%, mostly previously undiagnosed. Dementia is an umbrella term for chronic disorders that result in impairment in two or more cognitive domains, including memory loss, language, motor activity, object recognition, and disturbance of executive function. Although dementia would ideally be diagnosed by primary care physicians, this is not the norm. Detection of dementia by emergency clinicians allows a baseline cognitive status to be documented in the record and prompts patient and family to seek definitive evaluation for prognosis and planning. Most importantly, early recognition prompts additional history seeking from family and other collateral sources to reevaluate the chief complaint, which ultimately saves time and improves diagnostic accuracy.

Functional assessments, including activities of daily living (ADLs) and instrumental activities of daily living (IADLs), are important (Table 183.1). Functional decline can provoke ED presentation and may be the only manifestation of serious underlying disease. Functional impairment is relevant to disposition and predicts short-term repeat ED visits.

Routine evaluation of cognitive and functional status can be time-consuming. Given the emphasis on efficiency in the ED, appropriate identification of high-risk older adults may help emergency clinicians target patients for more detailed evaluation in the ED or for some other intervention. Recently published geriatric emergency department guidelines also recommend screening for high-risk patients. The Identification of Seniors at Risk (ISAR) tool is a recommended screening tool that incorporates elements of cognitive impairment and functional decline together to estimate risk (Box 183.1). Screening tools such as the ISAR highlight the interplay between cognitive impairment and
functional decline. Further work is needed on the development and validation of brief screening instruments.\(^3\)

### Box 183.1

**Identification of Seniors at Risk (ISAR) Tool**

1. Before the illness or injury that brought you to the emergency department, did you need someone to help you on a regular basis? (yes)
2. Since the illness or injury that brought you to the emergency department, have you needed more help than usual to take care of yourself? (yes)
3. Have you been hospitalized for one or more nights during the past 6 months (excluding a stay in the emergency department)? (yes)
4. In general, do you see well? (no)
5. In general, do you have serious problems with your memory? (yes)
6. Do you take more than three different medications every day? (yes)

Each “yes” response counts as 1 point, for a total score ranging from 0 to 6. A patient is considered at high risk when the score is 2 or more.

### Adapting Fundamental Principles of Geriatrics to the Emergency Department

Emergency clinicians should adapt fundamental principles of geriatrics for emergency practice such as shared decision making, a focus on risks and benefits of therapy, a focus on quality of life considerations, and interdisciplinary care. In contrast to a more holistic approach, traditional organ system or illness-based approaches will lead to greater intensity of service,\(^5,13\) with resulting increases in crowding, medical spending, and iatrogenic harm. The ED will need to be not only a critical care safety net but also a partner in managing care coordination. Care coordination can be defined as the conscious effort by two or more health care professionals to facilitate and coordinate the appropriate delivery of health care services for a patient—for example, when the emergency clinician speaks by phone with the primary care physician to discuss follow-up needs to ensure a safe discharge.

### Transitions in Care

Transitions in care, particularly from nursing home to ED, ED to inpatient, and ED discharge to home or nursing home setting, are...
potentially high-risk events. Omissions in documentation and lack of direct communication may lead to information gaps, particularly in the transition from nursing home to ED. Transitions in care may be riskier for older patients due to the complexity of their medical problems, usage of multiple medications, and cognitive and/or hearing impairment that may limit the patient’s ability to participate in history taking and disposition planning. Transitions in care may negatively affect older patients as a result of medication errors, adverse drug events, unnecessary treatments and hospitalizations, and lack of timely coordination of follow-up care. A number of groups, including the American College of Emergency Physicians, have identified management of transitions in care as a quality gap in emergency medicine and have advocated for greater vigilance around these transitions. Effective transitions in care for older patients requires communication between transferring and receiving providers, sharing of relevant information about patient preferences and clinical status, robust medication reconciliation, and detailed discharge planning, with the consideration of palliative care when appropriate.

Goals of Care and Palliative Care

Older patients with advanced and end-stage disease frequently present to the ED. A recent study examining ED use in the last months of life for older adults has found that 75% visited at least once during their last 6 months of life, and 51% visited the ED in the last month of life, with repeat visits and in-hospital death as common outcomes. For patients with advanced life-limiting disease, the role of the emergency clinician is a combination of curative care, such as infection management, and palliative care, meaning a patient-centered focus on quality of life, particularly symptom management. For patients for whom the focus may be on symptom management for end-of-life care, frequent complaints include agitation and delirium, anxiety, constipation, dyspnea, pain, pruritus, excessive oral secretions, stomatitis and nausea, vomiting, and diarrhea.

Prognostication in the ED setting is challenging, as it is communication with patients and families regarding goals of care in an inherently fast-paced ED environment. However, these interventions are nonetheless necessary because benefits of palliative care include improved patient satisfaction, reduced length of stay, cost savings, and improved outcomes. Even if the interdisciplin ary staff (eg, social worker, clergy, hospice case manager, palliative care specialist) are not immediately available in the ED, the role of ED staff must be facile in addressing end-of-life issues, including assisting in the transition to palliative care or hospice.

SPECIFIC DISORDERS AND CHIEF COMPLAINTS

The most common chief complaints in older ED patients are chest pain, shortness of breath, and abdominal pain. A major challenge in caring for older patients is that disease in old age—presentation, clinical course, response to treatment, outcomes—is usually modified by interaction with age-related changes. For example, atypical presentations may be due to a combination of age-related physiologic changes, age-related loss of physiologic reserve, interactions of chronic conditions with acute illnesses, and underreporting of symptoms.

Another challenge in caring for older patients is that chronologic age and physiologic age are not synonymous. There is great variability in senescence among older adults, so establishing baseline functional status is critical in shared decision making with the patient and family. Regardless, older patients are more susceptible to disease due to so-called homeostasis, a diminished ability to maintain homeostasis under stress.

Acute Coronary Syndrome

Cardiovascular heart disease is the leading cause of death in men and women older than 65 years. Many physiologic changes of aging occur in the cardiovascular system (see Table 183.2). Atypical presentations of acute coronary syndrome (ACS) occur more often in older patients. Chest pain at presentation occurs in only about 50% of patients with ST elevation myocardial infarction (STEMI) who are 85 years or older. Although chest pain may be absent, only 2% to 6% of older patients with ACS are actually asymptomatic. Other presenting symptoms may include dyspnea, syncope, shoulder or back pain, abdominal pain, weakness, fatigue, and delirium. One-third of women older than 65 years with acute myocardial infarction present with abdominal pain alone. Many of these presenting symptoms are nonspecific and are common to many other disease processes. As a result, the diagnosis of ACS may be delayed, and older patients may present instead with delayed complications, such as acute congestive heart failure.

Acute heart failure at presentation occurs in nearly 50% of STEMI patients 85 years or older compared to only 1.7% of STEMI patients younger than 65 years. Myocardial ischemia impairs left ventricular relaxation, which leads to an increase in left ventricular end-diastolic pressure (LVEDP). This increased LVEDP, superimposed on age-related decreases in left ventricular compliance, frequently results in elevated pulmonary capillary wedge pressure and heart failure.

Older patients with ACS have higher associated mortality. However, older patients often do not receive as aggressive treatment, in terms of referral for cardiac catheterization, as their younger counterparts, even though current American Heart Association (AHA) guidelines recommend no absolute age restrictions in revascularization therapy for non-STEMIs and STEMs. Another factor that supports cardiac catheterization in older adults is that there is an age-related increase in complications with thrombolytic medications, particularly intracerebral hemorrhage and free wall rupture. For older patients with acute myocardial infarction complicated by cardiogenic shock, recent AHA guidelines now recommend early revascularization across all age groups.

Abdominal Pain

Older ED patients with acute abdominal pain have about a sevenfold mortality risk compared to younger patients, and about

30% will require surgery. Atypical presentations are common. Several factors can complicate the ability to make a diagnosis based on the history and physical examination alone, including altered pain perception, aging effects on the immune system, medications that limit tachycardic response to stress, and decreased ability to mount a febrile response to infection. Sometimes, older patients will present only with generalized symptoms such as delirium, malaise, or dizziness when the cause is an acute abdominal condition. Laboratory values are frequently normal, despite the presence of surgical disease. Imaging studies, particularly computed tomography (CT), are often appropriate to facilitate diagnosis and are highly diagnostic in an older patient population.23

Consideration of intra-abdominal vascular catastrophe is important because the incidence of vascular disease increases with age. Vascular emergencies remain some of the most time-sensitive and highly morbid causes of abdominal pain in the older patient and should always be considered first, particularly for abrupt onset symptoms.24 Although the diagnosis of a ruptured abdominal aortic aneurysm (AAA) may be fairly straightforward in the older patient who has abdominal pain, hypovolemic shock, and a pulsatile abdominal mass, most patients lack this triad at presentation. AAA is commonly misdiagnosed as acute renal colic, and any older patient presenting with symptoms of new-onset nephrolithiasis should have imaging to evaluate the aorta for AAA.

Appendicitis is the third most common indication for abdominal surgery in the older patient population. Older patients have a higher incidence of perforation and mortality due to much higher rates of delayed diagnoses and/or presentations. Cognitive issues, altered pain perception, high stoicism, and transportation barriers may be factors in regard to a delayed presentation. Appendicitis historically has been misdiagnosed half of the time in older adults because many patients lack fever, anorexia, or leukocytosis. One-quarter of older patients have no right lower quadrant pain at all.

Biliary tract disorders are the most common cause of abdominal pain in the older adult, with the incidence of gallstones increasing with age. Cholecystitis is the most common indication for abdominal surgery in the older patient. About one-third of older patients with cholecystitis have no fever or leukocytosis. Additionally, about one-third of older adults with acute cholecystitis will present with minimal abdominal pain and an absence of peritoneal signs. Due to the poor vascularity of the gallbladder, older patients are at increased risk of complications such as perforation and emphysematous cholecystitis.

**Fig. 183.3.** Diagnostic approach to weakness by onset and focality. (From Anderson RS, Hallen SAM: Generalized weakness in the geriatric emergency department patient: an approach to initial management. Clin Geriatr Med 29:91–100, 2013.)

**Generalized Weakness**

Nonspecific complaints such as generalized weakness are consistently among the top ten presenting complaints for older ED patients. These poorly defined, nonspecific complaints have been variously described as dizziness, frailty, failure to thrive, generalized weakness, malaise, and fatigue. One study has found that 58% of older ED patients presenting with nonspecific complaints such as weakness developed a serious condition within 30 days.25 Important historical features include timing and focality of symptoms.26 Neuroimaging can be helpful if the weakness is acute or localized because around 75% of the subset of older weak patients with acute focal or localized weakness are ultimately found to have stroke or intracranial hemorrhage. Research suggests that three categories of illness—infections, metabolic abnormalities, and malignancies—were found in almost all patients presenting with nonspecific complaints of weakness.25
Infections

Older patients experience an increased incidence of severe infection and severe sepsis with advanced age. Mortality from sepsis approaches 40% for patients older than 85 years. Aging effects on immunity include a decline in cell-mediated immunity and antibody production. Older patients may also have multiple risk factors for sepsis (Fig. 183.4) including comorbid diseases, exposure to instrumentation, malnutrition, and institutionalization. For example, studies have shown that an increasing chronic disease burden correlates with increasing hospitalization rates for community-acquired pneumonia in older adults.

With aging, the ability to generate a fever response in response to pyrogens (bacterial endotoxins) is decreased. Because of this blunted fever response, and because medication use or cardiac disease may limit tachycardic response to infection, older patients may have systemic inflammatory response syndrome (SIRS)—negative sepsis. Research has shown that abnormal triage vital signs in adults 75 years and older have poor sensitivity (73%) and specificity (50%) for predicting death or ICU admission. It is important that emergency clinicians look more broadly than just the typical SIRS criteria to suspect and diagnose sepsis accurately. For example, in the long-term care population, in whom there are particularly high rates of cognitive impairment, Current Infectious Diseases Society of America (IDSA) guidelines define suspected infection as fever plus a decline in functional status—confusion, incontinence, falls, decreased mobility, reduced food intake, failure to cooperate with staff.

Management of suspected sepsis in older patients is similar to that for younger patients, with an emphasis on early identification of sepsis, fluid resuscitation, and early and appropriate antibiotics. Just as with younger adults, older patients with sepsis have improved mortality with comprehensive sepsis treatment. Older patients are more dependent on having an adequate preload to increase cardiac output in response to sepsis because the ability to raise the heart rate is blunted. However, aging-associated diastolic dysfunction is common, and fluid resuscitation goals may need adjustment if patients develop hypoxia or hypervolemia. In regard to the choice of empirical antibiotics, sepsis in older patients compared to younger patients is more likely to be due to respiratory (relative risk [RR], 1.29) or genitourinary (RR, 1.38) infections, with pneumonia as the single most common cause of sepsis. Management of suspected sepsis in older patients, particularly in those with a poor prognosis, also includes consideration of patient and family preferences and goals of care.

KEY CONCEPTS

- We are in the midst of a silver tsunami, with 10,000 Americans turning 65 every day. Older ED patients have the greatest resource use, longest lengths of stay, and highest admission rates of any age group.
- Delirium is underrecognized by emergency clinicians; recognition of delirium should prompt investigation for life-threatening emergencies, including infection, metabolic abnormalities, and acute coronary syndrome (ACS).
- Many older patients with ACS present without chest pain, especially females and patients older than 85 years. ACS in older adults is more often complicated by acute heart failure due to age-related decreases in left ventricular compliance. Recommendations regarding medical and revascularization therapy in those with non-STEMI and STEMI have no age limitations.
- Almost one-third of older ED patients presenting with abdominal pain are ultimately found to have a surgical condition causing the abdominal pain. Biliary tract disorders are the most common cause of abdominal pain in the older adult.
- Nonspecific complaints such as generalized weakness are among the top ten presenting complaints for older ED patients. Acute onset and focality of symptoms increase the likelihood of stroke or intracranial hemorrhage.
- Mortality from sepsis approaches 40% for patients older than 85 years, with respiratory and genitourinary infections being the most common sources. Older adults with serious infection may have SIRS-negative sepsis.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
1. Almost one-third of the time. The absence of chest pain is not frequent, only 2% to 6% are asymptomatic. Women have painless presentations of equal severity as typical cases. Although atypical cases are more common, only 2% to 6% are asymptomatic. Women have painless presentations more than men, and present with abdominal pain almost one-third of the time. The absence of chest pain is not uncommon.

2. The absence of chest pain is rare. The presence of chest pain is likely to have fever and signs or symptoms from the infection. Blood cell count, as well as a normal differential. They are less likely to have fever and signs or symptoms from the infection process. They are more likely to have complications and suffer long-term morbidity or mortality.

3. The most common underlying causes of complaints of nonspecific weakness are infection, metabolic derangements, and malignancy. Weakness is a part of natural aging.

CHAPTER 183: QUESTIONS & ANSWERS

183.1. The presentation of infection in older patients differs from the presentation in younger patients. Older patients are more likely to have which of the following?

A. Benign clinical course
B. Elevated inflammatory markers, such as erythrocyte sedimentation rate and C-reactive protein
C. Fever
D. Left shift of the white blood cells
E. Normal white blood cell count

Answer: E. Older patients are more likely to have a normal white blood cell count, as well as a normal differential. They are less likely to have fever and signs or symptoms from the infection process. They are more likely to have complications and suffer long-term morbidity or mortality.

183.2. Which of the following statements is true regarding acute myocardial infarction (AMI) in older adults?

A. Atypical presentations portend a more benign course.
B. Atypical presentations increase with age.
C. Painless AMIs occur more commonly in men.
D. The absence of chest pain is rare.
E. Up to 30% of older patients with AMI are asymptomatic.

Answer: B. Atypical presentations of AMI increase with age and are of equal severity as typical cases. Although atypical cases are frequent, only 2% to 6% are asymptomatic. Women have painless presentations more than men, and present with abdominal pain almost one-third of the time. The absence of chest pain is not uncommon.

183.3. A 74-year-old man with a history of hypertension and hyperlipidemia presents to the ED with acute onset of severe, nontraumatic, left flank pain. His vital signs include a heart rate of 72 beats/min and blood pressure of 120/70 mm Hg. Which approach to his care would be most appropriate?

A. Arrange for him to be in the observation unit overnight for serial abdominal examinations to help clarify his diagnosis.
B. Consider abdominal aortic aneurysm only after the patient’s urinalysis and renal ultrasound are negative for nephrolithiasis.
C. Diagnose him with nephrolithiasis without any further testing.
D. Evaluate for a possible abdominal aortic aneurysm.

Answer: D. Vascular disease prevalence increases with age. Vascular emergencies remain some of the most time-sensitive and highly morbid causes of abdominal pain in the older patient and should always be considered first, particularly for abrupt-onset symptoms.

183.4. Which of the following statements is true about complaints of nonspecific weakness in older ED patients?

A. Admission to a skilled nursing facility for failure to thrive should be the rule.
B. Emergency clinicians should assume that the weakness is a stroke until proven otherwise.
C. The most common underlying causes of complaints of nonspecific weakness are infection, metabolic derangements, and malignancy.
D. Weakness is a part of natural aging.
**Answer:** C. With nonspecific weakness, infections, metabolic abnormalities, and malignancies are the most common findings in older patients. Nonspecific complaints such as generalized weakness are consistently among the top ten presenting complaints for older ED patients. Important historical features include timing and focality of symptoms. If patients have acute focal weakness, a stroke or intracranial hemorrhage is very likely. However, in the absence of focal weakness, medical causes are more likely.

183.5. How does the presentation of abdominal pain in older adults differ from that in younger adults?

A. Bedside abdominal palpation and examination is the emergency clinician’s most sensitive tool.

B. Older patients are less likely to have a surgical emergency.

C. Older patients often have delayed presentations.

D. Older patients uniformly mount a febrile response when they have a surgical emergency.

**Answer:** C. Older patients often have delayed presentations of abdominal emergencies. Cognitive issues, altered pain perception, high stoicism, and transportation barriers may be factors in delayed presentation. Older patients are more likely to have a surgical cause of their abdominal pain. Imaging studies, particularly computed tomography, are often appropriate to facilitate diagnosis and are highly diagnostic in the older patient population.
Geriatric Trauma

Jeremiah D. Schuur | Zara Cooper

PRINCIPLES

Older adults make up a growing proportion of trauma patients in emergency departments (EDs). US trauma systems and management principles were developed in the 1970s and were based primarily on advances from military medicine and designed to serve younger adult patients. Although the general principles of trauma care for younger adults apply to older adults, there are special considerations for the older trauma patient. This chapter focuses on evaluation and management decisions for trauma in older patients that may differ from those in younger adults.

Background and Importance

There is no standard definition of the term geriatric trauma in the literature; studies include patients older than 45 to 65 years. Risk-adjusted analyses have demonstrated patients older than 55 years to be at higher risk of mortality, and some studies further stratify older adults into the oldest old group, those older than 80 or 85 years. In this chapter, unless noted, we are referring to patients 65 years and older. The literature on trauma in older adults has several limitations. Older adults are frequently excluded from clinical trials, a limitation in considering high-risk interventions such as surgery or invasive hemodynamic monitoring. Furthermore, studies conducted using trauma databases include only trauma center patients evaluated by a trauma team; the results may not be generalizable to non–trauma center ED populations.

Demographics and Epidemiology

The US population is aging, and older adults are living more independently and have more active lifestyles, which explains the dramatic rise in geriatric trauma. More than one in eight Americans were aged 65 years or older in 2012, whereas by 2030 one in five will be 65 years or older.1 In 2011, US adults aged 65 and older accounted for almost 13% of all injury-related ED visits, and this percentage is expected to increase with the aging of the population.2

Older trauma patients have increased morbidity and mortality owing to the severity of injury, presence of comorbid conditions, and independent effects of age. In similar accidents, older adults sustain more severe injuries than younger adults, a strong predictor of mortality. In 2010, unintentional injury was the ninth leading cause of death among those older than 65 years.3 Older adults are more likely to have significant underlying medical conditions that limit their physiologic response to injury and increase the risk of death after trauma, especially in less severe injuries.4 Age is independently predictive of morbidity and mortality, even when controlling for comorbidities and the Injury Severity Score (ISS).4

Mechanisms of Injury

Falls are the leading mechanism of injury and the leading cause of injury-related death in patients older than 65 years.5 In 2013, there were 2.5 million ED visits for falls among those 65 years and older, and one-third were hospitalized. Up to one-third of older adults sustain a significant fall each year, and serious injuries occur in up to 25%. Most falls are from standing and occur at the older adult’s place of residence. Risk factors for falling include, in decreasing relative risk, weakness, balance or gait deficit, visual deficit, mobility limitation, cognitive impairment, impaired functional status, and postural hypotension. Up to 10% of those who fall sustain a major injury, with head injury being the most frequent.6 Although the height of the fall is associated with severity, falls from standing carry significant risk for older adults; same-level falls result in serious injury (ISS > 15) 30% of the time in older patients, and peri-injury mortality from low falls is up to 10%.7

Motor vehicle accidents (MVAs) and pedestrians struck by a motor vehicle are the second and third most frequent causes of trauma in older adults.8 Older adults are more likely than younger adults to be involved in daytime crashes occurring close to home. A detailed crash history is important, and single-vehicle crashes should raise the suspicion that a medical problem caused the crash (eg, syncope, myocardial infarction, stroke), and an evaluation for coincident events leading to trauma should be undertaken.
BOX 184.1

Ohio Prehospital Geriatric Trauma Triage Indicators

- Trauma patients ≥70 years are defined as having suffered geriatric trauma.
- If an injured older adult has any of the geriatric indicators, he or she must be transported directly to a trauma center.

GERIATRIC ANATOMIC INDICATORS
- Injury sustained in two or more body regions

GERIATRIC PHYSIOLOGIC INDICATORS
- Glasgow Coma scale score <15 with a known or suspected traumatic brain injury
- Systolic blood pressure < 100 mm Hg

GERIATRIC MECHANISM INDICATORS
- Fracture of one or more proximal long bones (humerus or femur) sustained in a motor vehicle accident
- Pedestrian struck by a motor vehicle
- Falls from any height—including standing—with evidence of a traumatic brain injury

Adapted from State of Ohio, State Board of Emergency Medical Services, Trauma Committee: Geriatric trauma task force report and recommendations. www.publicsafety.ohio.gov/links/ems_geriatric_triage.pdf.

During the trauma management process. Older adults are more likely to be struck by a motor vehicle than younger pedestrians because of poor eyesight, limited mobility, and slower reaction time. Pedestrians who are struck sustain significant injury patterns and have the highest fatality rate of all geriatric injuries, 30% to 55%.

Thermal injuries, self-injury, and elder abuse are less common but important injury patterns in older adults. Thermal injuries such as burns and smoke inhalation occur more frequently and are more severe in older adults owing to decreased mobility and physiologic skin changes. Older adults have a lower likelihood of attempting self-injury but a higher likelihood of completing suicide attempts than any other age group, with men at higher risk. Elder abuse is a complex problem that can involve psychological, social (eg, financial), and physical abuse. Studies have found that around 5% of older adults self-report abuse in the previous month, although lower rates of physical abuse are reported to protective services. All older adults with injuries should be asked if they feel safe at home and if there is anyone in their life who is threatening or injuring them.

Anatomy and Physiology

Older adults are more vulnerable to trauma owing to age-related changes in anatomy, physiology, and pathophysiology. Aging’s main effects on human physiology are decreased functional reserve, seen across organ systems, due to reductions in the volume of viable tissue and intrinsic function of the tissues. Older adults are more likely to have comorbidities and to be taking multiple medications that affect their likelihood to get injured and their response to injury. The assessment of the geriatric trauma patient should be informed by these important differences.

Pathophysiology

Due to decreased functional reserve, older adults are less able to compensate for physiologic demands of hypovolemia and stress resulting from hemorrhage associated with trauma. Although older adults in a good state of health have sufficient reserves to accomplish activities of daily living, when they are stressed by acute trauma and the subsequent response to injury, the decrease in physiologic reserve can lead to a more rapid progression to tissue hypoperfusion and organ failure, a common cause of death in older trauma patients.

Comorbidities

Older adults are likely to have significant comorbidities at the time of injury. The percentage of older adults experiencing at least one of five chronic diseases—arthritis, stroke, chronic lower respiratory tract disease, coronary heart disease, and diabetes mellitus—varies from 15% to 47%, with only 33% of men and 25% of women having none of these comorbidities.

Effect of Medications

Medication use is common in older adults. A representative survey of community-dwelling US adults (aged 57–85 years) has found that 81% use at least one prescription medication, and 29% use five or more prescription medications. Approximately 5% of older adults are on warfarin, a growing number are on novel oral anticoagulants, and more than 30% are on an antiplatelet agent, increasing the likelihood and severity of hemorrhage. Medications increase the likelihood of older adults experiencing a traumatic accident (eg, sedative-hypnotics causing falls). Some, such as beta blockers, affect the physiologic response to trauma. Medications’ effect on vital signs should be considered during the primary survey, and a full medication history should be taken early in the secondary survey.

CLINICAL FEATURES

Modifications to the Trauma Assessment of Older Adults

A systematic trauma assessment, including a primary and secondary survey and resuscitation, should be conducted in older adults (see Chapter 33). However, many signs and symptoms of injury in the younger adult, such as hypotension, tachycardia, and pain, will be mild or absent in many older adults. Normal vital signs should not be reassuring because significantly injured older adults often display delayed hemodynamic signs of injury, such as tachycardia or hypotension.

Primary Assessment and Resuscitation

Airway

Establishing and maintaining a patent airway is the primary objective. Because older patients are likely to have multiple risk factors for a difficult airway, emergency clinicians should perform a systematic airway assessment, focusing on the ability to mask ventilate, endotracheal intubation, and a cricothyrotomy. Early intubation is indicated for unstable patients, as defined by signs of shock, altered mental status, and significant chest trauma. Because direct laryngoscopy is more difficult in older adults because of limited cervical mobility and less mobility at the temporal mandibular joint, the use of videolaryngoscopy is recommended. Cricothyrotomy is more likely to be complex in older adults because they are more likely to have had scarring from neck surgery, radiation, or neck tumors, which distort normal anatomy. Older patients are also more likely to be anticoagulated. Finally, rapid sequence intubation (RSI) medications should be tailored to the older adult (see Chapter 1).
Breathing

High-flow supplemental oxygen should be initially applied to all patients, including those with chronic pulmonary disease. The short-term benefits of avoiding hypoxia and increasing oxygen reserves are important because older adults have a reduced pulmonary reserve, which can cause systemic pulmonary injuries to overwhelm the ability to oxygenate and ventilate. The respiratory rate should be closely followed because older adults are more likely to tire and can rapidly decompensate as a result of pulmonary injuries or aggressive fluid resuscitation.

Circulation

Older patients are particularly vulnerable to shock because their blunted response to stress and limited physiologic reserve increase the risk of organ dysfunction. The assessment of circulatory status is complicated because responses to hypovolemia, such as tachycardia and hypotension, are reduced by physiologic changes and medications (eg, beta blockers). Vital signs are insensitive because normal blood pressure does not reliably exclude significant hemorrhage or shock. Systolic hypertension is common among older adults, so normotension may indicate significant hypovolemia. It is important to remember that the therapeutic window for cardiac preload is narrow, and inadequate monitoring of fluid status may lead to errors in volume resuscitation. Vitals signs should be frequently reassessed; in older trauma patients, trends are more important than specific cutoffs.

First, life-threatening bleeding should be identified and controlled. This includes external bleeding, such as hemorrhage from scalp injuries, which can be significant in older adults. The focused assessment with sonography in trauma (FAST) modality has emerged as an important adjunct to the primary survey but has not been specifically studied in older patients. A urinary catheter can be placed to monitor urine output, although this is a less sensitive predictor of renal blood flow than in younger patients. Invasive hemodynamic monitoring is appropriate for some severely injured older adults such as those with shock and poor ejection fraction, but routine use is not justified.

Fluid resuscitation should balance the risk of hypoperfusion with the unclear benefit of fluids and blood. We recommend beginning initial resuscitation with blood in the patient with significant bleeding, signs of hemodynamic instability, or significant injuries (eg, unstable pelvic fracture) because older adults do not tolerate large-volume resuscitation well and can easily become fluid-overloaded. In patients in whom there is no obvious source of blood loss, incremental boluses (eg, 500 mL) of warmed isotonic crystalloid should be used for resuscitation. The hemodynamic status should be reassessed frequently after small fluid boluses to avoid causing pulmonary edema and respiratory failure from fluid overload.

Prompt reversal of anticoagulation is important because a significant number of older patients are on warfarin, and others may have pathologic coagulopathy. Specific considerations for reversing coagulation abnormalities in older trauma patients are the volume of reversal agents required and the corresponding risk of fluid overload. Prothrombin complex concentrates (PCCs) require minimal volume compared with fresh-frozen plasma (FFP) but are more costly. We recommend early use of vitamin K and a PCC in older adults with major injuries who are on warfarin. In EDs that do not have rapid availability of PCCs, FFP should be given.

Disability

Evaluation of older adults for disability includes examination for traumatic brain injury (TBI), spinal cord injury (SCI), and vertebral fractures and injuries. The primary neurologic examination of older adults should focus on mental status, verbal responsiveness, pupil responsiveness, and gross motor examination. The Glasgow Coma Scale (GCS) is often used to detect mental status changes after TBI but was not designed for this purpose and lacks sensitivity for mild injuries. Any GCS score less than 15 is concerning for TBI, and a GCS score below 8 is highly predictive of a poor outcome. Subtle changes in mental status such as confusion or decreased alertness or symptoms such as headache may be the only signs of TBI. The mental status examination in older adults is complicated by comorbidities such as previous stroke and the increasing prevalence of cognitive impairment in older adults, including dementia and delirium. Delirium can be the cause of traumatic injury, such as falls, or can be the result of traumatic injuries. Abnormal pupillary responsiveness or motor function should raise concerns for significant intracranial hemorrhage (ICH), with associated increased intracranial pressure (ICP). Ultimately, no combination of historical features and physical findings has been shown to reliably predict the absence of intracranial injuries in the older trauma population. Brain computed tomography (CT) is indicated for older adults with head trauma, significant multisystem trauma, or symptoms or signs of TBI, because no clinical decision rule has been validated in older trauma patients.

Older adults are at higher risk of vertebral fractures, and cervical fractures in particular, and they are more likely to sustain SCI as a result of trauma. Clinical decision tools that are available for cervical spine imaging in trauma are not recommended for older adults. The Canadian C-Spine Rule (CCR) classifies all patients 65 years and older as inherently high risk, requiring radiography; the derivation study found that age older than 65 years had an odds ratio of 3.7 (95% confidence interval [CI], 2.4–5.6) for clinically significant cervical spine injury. The National Emergency X-Ray Utilization Study (NEXUS) included all ages but found that patients aged 65 years and older had a relative risk of 2.1 (CI, 1.8–2.6) for clinically significant cervical spine injury. Other studies have shown that only 45% of older patients with cervical spine fractures had cervical spine tenderness on examination; therefore, the absence of tenderness cannot be used to rule out cervical spine injury in older patients. Older adults are also at increased risk of thoracic, lumbar, and sacral vertebral fractures, for which CT is more sensitive than the physical examination or plain radiography.

Exposure

Older trauma patients are more likely to develop hypothermia because of physiologic changes and mechanisms of injury. Because the skin thins with aging, and muscle and fat mass decrease, normal thermoregulatory mechanisms are no longer intact. Prolonged immobilization with exposure to the elements is common when older adults fall and are unable to get back up, leading to hypothermia, dehydration, and renal insufficiency. A rectal temperature should be routinely taken, and hypothermia should be rapidly treated. Because skin breakdown and relatively minor wounds can cause serious complications in older patients, older adults should be removed from backboards as soon as possible and examined for pressure ulcers. Older patients are more likely to require a tetanus booster, and older trauma patients should receive tetanus immunization if it is not up to date.

Secondary Assessment

The stable geriatric trauma patient requires a thorough secondary assessment. A complete history should be obtained from the patient or a care provider, with particular emphasis on corroborating the accident history, past medical history, medications and...
allergies, and social history, including baseline functional status and living arrangements. Patients should be screened for alcohol and substance abuse and elder abuse.22

Laboratory Testing

We recommend the following routine laboratory tests: complete blood count, comprehensive metabolic profile, coagulation studies (international normalized ratio [INR]), lactic acid level, base deficit, urinalysis, cardiac enzyme levels, and toxicology. An elevated lactic acid level and base deficit, which can signal tissue hypoxia and organ dysfunction, are predictive of mortality and can help determine the prognosis in older adults with normal vital signs. Electrocardiography and cardiac monitoring are advised because many older patients have cardiac causes or complications of their traumatic event.

Imaging

Older trauma patients deemed unstable should undergo portable plain radiography of the chest and pelvis. CT is the imaging modality of choice for stable older trauma patients; plain radiography is less sensitive. Older adults have less additional lifetime risk from the radiation associated with CT scans than younger adults owing to their lower life expectancy, but they are at greater risk from contrast-introduced nephropathy. When possible, intravenous (IV) contrast should be avoided, and renal protective strategies should be used, including IV fluids, bicarbonate, and N-acetylcysteine.

SPECIFIC DISORDERS

Traumatic Brain Injury

TBI is common in older adults, can occur with minimal head trauma, and can be asymptomatic. Overall mortality rates among older patients with TBI range from 30% to 80%, and increasing age is an independent predictor of disability and mortality in patients with TBI. Physiologic changes of aging and the frequent use of anticoagulant and antiplatelet medications increase the likelihood and severity of TBI in older adults. With aging, the size of the brain decreases by 10% on average, resulting in less tortuous bridging veins and increased intracranial free space. The atrophied brain is more mobile within the skull, and trauma is more likely to shear bridging veins, leading to ICH.

Differential Diagnosis

If there is concern for intracranial injury, cranial CT is indicated, regardless of reported loss of consciousness. Diagnosis of TBI is more difficult in older adults because cognitive impairment is more common and increased intracranial free space can allow the accumulation of blood without changes in mental status. Clinical variables alone are insufficient to identify all cases of significant intracranial injury reliably following trauma in older patients; both the New Orleans Criteria (exclude age >60 years) and Canadian Head CT Rule (excludes age ≥65 years) exclude older adults.

Management

Treatment of TBI includes supportive care, rapid reversal of anticoagulation, and evaluation for decompressive surgical intervention. Supportive care aims to avoid cerebral hypoxia and hypoperfusion, which are significant predictors of adverse outcomes. All patients should initially receive high-flow oxygen to maintain high oxygen saturation. Patients with hypercarbic respiratory conditions (eg, chronic obstructive pulmonary disease) require an individualized determination of the appropriate oxygen saturation. Preventing cerebral hypoperfusion requires close monitoring of hemodynamic parameters, including blood pressure and urine output; individual patients may benefit from invasive hemodynamic monitoring. Early neurosurgical consultation is indicated to assess the need for and usefulness of surgical ICP monitoring and decompression. Current guidelines for ICP management have not been studied in older adults with TBI.

Prompt reversal of anticoagulation with a PCC, or FFP if PCC is unavailable, is indicated for older adults taking warfarin. The evidence supporting PCCs has shown that immediate administration of PCC is associated with more rapid reversal and less hematoma growth than vitamin K and FFP, including one study of years trauma patients.23 To date, however, there have been no prospective randomized studies demonstrating better outcomes.24 Treatment or reversal of antiplatelet agents and other anticoagulants, including low-molecular-weight heparins and novel oral anticoagulants, is based on expert opinion rather than clinical trial data. Thus, EDs should determine local practice in coordination with their trauma and neurosurgery consultants.

Disposition

TBI in older adults is associated with significant morbidity and mortality, but ED prognosis is not precise. Negative prognostic factors include increasing age, anticoagulation,17 use of antiplatelet medications, greater severity of TBI, and lower GCS score.25 Although many patients with severe injuries, significant comorbidities, or anticoagulation have no chance of a meaningful outcome, others can return to living in the community.26 Patients with moderate or severe TBI, or any TBI and anticoagulation, require neurosurgical consultation and intensive care in which frequent neurologic checks and rapid reversal of anticoagulation can be accomplished. This is problematic for emergency clinicians at hospitals without neurosurgical coverage because it requires transferring patients with a grave prognosis, potentially for long distances. When an older adult with TBI is being transferred, reversal of anticoagulation and prevention of hypoxia and hypotension are important early management steps. Older patients with isolated head trauma, normal cranial CT, and normal INR are generally safe for discharge if they have a safe environment, responsive care provider, and reliable follow-up.27

Vertebral Fractures and Spinal Cord Injuries

Age-related changes to the vertebral bones, intervertebral disks, and spinal canal place older adults at greater risk of vertebral fractures, result in a greater likelihood of SCI, and make physical examination and diagnostic imaging results less accurate. Based on radiologic studies, approximately 25% of patients older than 65 years have cervical stenosis, and 90% of men older than 50 years and 90% of women older than 60 years have evidence of degenerative changes in the cervical spine. These changes have the effect of creating leverage on the spinal column when an external force is applied, such as in a fall with an impact to the head, concentrating force on weakened bone and increasing the risk of fracture and SCI.

Differential Diagnosis

Spinal canal stenosis and the resulting spinal cord compression are clinically manifested as a myelopathy, with impairment of coordination, gait, bowel or bladder function, and motor or sensory function, or both. Geriatric patients with vertebral injuries and SCIs are more likely to sustain incomplete neurologic...
injuries of lesser severity than younger patients, largely because they have lower force injuries.

In cases of suspected vertebral fracture or SCI, continued immobilization, spine surgery consultation, and admission are indicated. Older adults are at higher risk for SCI without obvious radiographic abnormality owing to spinal cord stenosis and cervical kyphosis. Evaluation for ligamentous injury and SCI with magnetic resonance imaging (MRI) is appropriate in patients with focal neurologic deficits. Most geriatric vertebral fractures and SCIs are represented by three types of injuries: (1) central cord syndrome; (2) cervical extension-distraction injuries; and (3) odontoid fractures.

Central Cord Syndrome. Central cord syndrome (CCS) is characterized by weakness disproportionately greater in the arms than in the legs after a hyperextension injury. Most cases of CCS in older adults are the result of hyperextension injuries in patients with canal stenosis and no bony fracture. In CCS, injury may result from anterior compression of the cord by osteophytes or pinching of the cord posteriorly by the ligamentum flavum, resulting in bleeding into the central part of the cord or with axonal disruption in the lateral columns of the spinal cord. Injuries associated with CCS syndrome are typically stable and require immobilization with a hard collar. Surgical decompression may be indicated. Patients with symptoms concerning for CCS and without fracture should undergo MRI.

Cervical Extension-Distraction Injury. Cervical extension-distraction injury occurs in the patient with reduced cervical range of motion. A hyperextension injury of the cervical spine and external signs of trauma to the forehead or face in an older adult should raise suspicion for an extension-distraction injury. The patient may report that she or he is able to touch the pillow on the bed with the back of the head, which she or he was unable to do before the injury. This is a result of the fracture, which opens and lengthens the anterior column of the spine, resulting in the term open book fracture. Clinical symptoms can range from nerve root compression to severe SCI. These fractures are typically unstable and require surgical fixation.

Odontoid Fractures. Fracture of the C2 vertebral body, specifically the odontoid process, is usually the result of a fall with impact to the head, resulting in anterior or posterior displacement of the odontoid process. Although most odontoid process fractures are displaced, less than 10% cause neurologic deficits. Type II odontoid fractures, at the base of the dens at its attachment to the body of C2, are the most common C-spine fractures in older trauma patients. There is no agreement on the best approach to manage type II odontoid fractures, types I and III fractures are typically managed nonoperatively with neck immobilization.

Thoracic Trauma

Older adults are at increased risk of rib and sternal fractures, pulmonary contusions, and their complications with low-force injuries. More than 50% of older patients admitted to hospital with rib fractures sustained them during a fall, and a significant number occurred during low- or moderate-speed MVAs.

Differential Diagnosis

The risk of pneumonia and complications increases with the number of ribs fractured. Pulmonary contusions are more frequent with minimal trauma, even without accompanying rib fractures, and can cause significant morbidity and mortality in older adults.

Diagnostic Testing

Chest CT is recommended for older patients with significant chest trauma, multiple rib fractures by plain film, or respiratory complications from trauma.

Management

Patients with significant chest trauma require airway monitoring, with consideration of early intubation to anticipate their clinical course, pulmonary therapy, and pain control. Pain control is of particular importance because rib fractures will lead to splinting and atelectasis and increase the risk of pneumonia. Analgesia can be administered with epidural analgesia, paravertebral analgesia, or opioids orally or with patient-controlled analgesia.

Disposition

Geriatric trauma patients with severe pain from rib fractures should be hospitalized to manage pain adequately and safely. Those with flail segments, multiple rib fractures, or pulmonary contusions may require intensive care unit admission.

Abdominal Trauma

Older adults are more likely to sustain intra-abdominal injuries and have higher mortality from such injuries. The general management principles are similar to those in younger adults, although there is less clinical evidence supporting nonoperative management (NOM) and angiographic embolization of solid organ injuries.

Differential Diagnosis

The focus of the emergency clinician is on the early diagnosis of intra-abdominal injuries, vigilant hemodynamic monitoring, and early resuscitation. Clinical manifestations of serious abdominal injury in older patients are often minimal. Reliance on the abdominal examination may lead to missed abdominal injuries, and the emergency clinician should use a low threshold of suspicion to carry out imaging.

Diagnostic Testing

The FAST examination should be part of the initial evaluation and can be repeated as part of ongoing hemodynamic monitoring, although it is insensitive for solid organ injuries. Older patients with abdominal tenderness, significant multisystem trauma, or hemodynamic instability should undergo CT scanning. Angiography is a reasonable option for the older trauma patient with solid organ injury and a blush or extravasation on CT.

Management

Although advanced age was initially an exclusion from NOM of solid organ injuries, there is more than a decade of evidence showing that carefully selected older adults are candidates for NOM. In several case series, approximately 80% of older adults with splenic injuries were successfully managed nonoperatively, with the caveat that grade III injuries were more likely to fail NOM, and all geriatric patients with grade IV or V injuries required an operation. There are limited data on NOM of liver injuries in older adults.

Extremity Injuries

Fractures are the most common injuries in older adults with trauma due to osteopenia. Fractures that affect mobility and the
ability to live independently, such as hip fractures, are associated with significant perioperative and 1-year mortality in older adults.

**Differential Diagnosis**

The most common fractures sustained by older adults, in order of frequency, are distal radius fractures (Colles' fractures), proximal humerus fractures, and elbow fractures, which usually occur during a fall onto an outstretched arm. Older adults with proximal humoral fractures can have remarkably few symptoms.

The most common lower extremity fractures in older adults are ankle fractures, hip and pelvic fractures, and tibial plateau fractures. Pelvic fractures can occur with relatively little force in older adults and fracture patterns are similar between older adults and younger adults, with lateral compression fractures more common than anteroposterior fractures. In older adults, both fracture types are associated with significant hemorrage. Overall pelvic fracture mortality is 9% to 30% and up to 81% in older patients with open pelvic fractures. Emergent treatment of pelvic fractures consists of hemodynamic monitoring, resuscitation with blood, stabilization of the fracture with wrapping or external fixation, and control of bleeding, with consideration of embolization to treat retroperitoneal hemorrhage. Hip fractures are common in older adults, occurring annually in approximately 1% of men and 2% of women. Whereas isolated hip fractures are not associated with significant immediate hemorrhage or mortality, such as seen in pelvic fractures, they are associated with an 8% to 30% 1-year mortality.

**Diagnostic Testing**

Hip fractures are usually seen on plain x-ray films (sensitivity ≥ 90%) and CT scans, but occult fractures are a well-described phenomenon in older adults. Patients with the inability to ambulate or who have persistent pain after trauma require further evaluation; MRI and bone scanning are useful imaging studies to delineate the pathology. Ultrasound-guided femoral nerve block or fascia iliaca compartment block can improve analgesia and reduce the use of opioids in the ED.

**Management**

Older adults with fractures have better outcomes with early surgery (<72 hours) and care in a distinct orthogeriatric service. Emergency clinicians should consider transferring older adults with hip fractures to hospitals with such services.

**DISPOSITION: END-OF-LIFE CONSIDERATIONS**

Emergency clinicians are faced with difficult decisions regarding prognosis, the effectiveness of aggressive care, and end-of-life decisions in geriatric trauma. Older trauma patients have a uniformly worse prognosis than younger adults. Several factors that portend a grave prognosis from the ED include a GCS score of 3, a GCS score below 8 with anticoagulation, and hemodynamic instability from internal hemorrhage with anticoagulation. However, initial injury in the ED does not predict an individual patient's long-term prognosis perfectly, and emergency clinicians have not traditionally withheld trauma care, including transfer to a trauma center and involvement of trauma surgeons. Emergency clinicians should discuss end-of-life decisions, such as intubation, cardiopulmonary resuscitation, transfer, and surgery, with patients, family members, caregivers, and surgical consultants. Although age alone is not an indication to withhold aggressive treatment, comfort measures may be more appropriate than transferring patients to a trauma center in select cases with a grave prognosis and when the patient's goals of care are known.

**KEY CONCEPTS**

- We recommend that advanced age (≥70 years) be used as triage criteria for transfer to a trauma center and activation of a trauma team.
- Emergency clinicians should consider shock in all older trauma patients. Because vital signs, including tachycardia and hypotension, are unreliable to detect hemodynamic instability in older adults, emergency clinicians should closely follow alterations in mental status, urine output, and skin perfusion.
- Older adults are at significant risk from shock, yet they are also at risk from aggressive resuscitation. Resuscitation should be rapid but should also include frequent reassessments of vital signs, respiratory status, and other potential indicators of shock. Start resuscitation with blood in the patient with significant bleeding, signs of hemodynamic instability, or significant injuries (eg, unstable pelvic fracture).
- Older patients are at high risk of hypothermia and develop pressure ulcers more rapidly. They should be removed from backboards as soon as possible, and rectal temperature should be routinely checked in the secondary survey.
- Clinical decision tools for radiographic imaging have generally excluded older patients. A low threshold for imaging should be used for older adults with trauma, and CT should be used as the primary modality, except for extremity imaging.
- Falls are the leading cause of injury-related death in older adults, and ground-level falls can result in major injuries. Although there is debate about the effectiveness of interventions for secondary prevention of falls, we advise that emergency clinicians assess gait and notify the primary care physician, and we recommend close follow-up at a minimum. Engaging social services, including arranging a home safety visit, may be beneficial.
- Among patients with TBI or hemorrhagic injuries, anticoagulation predicts poor outcome. Rapidly reverse warfarin with a PCC or FFP if a PCC is unavailable.
- Rib fractures and pulmonary contusions are associated with poor outcomes in older patients. Patients with flail chest, two or more rib fractures, or pulmonary contusions should be hospitalized for monitoring, pulmonary care, and analgesia.
- Older adults with hip fractures have improved survival on a dedicated orthogeriatric service. Consider transfer of patients to hospitals with this service available.
- Routinely screen for elder abuse. A valid screening question is: “Has anyone close to you tried to hurt you or harm you recently?”

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
A 76-year-old man is brought to the emergency department (ED) after a fall at home. The paramedics tell you that he slipped in the shower and struck his head on a tile floor. The patient is awake and alert. He is unsure if he lost consciousness and complains of headache. When you obtain a computed tomography (CT) scan of his head, it reveals evidence of a cerebral contusion. The paramedic tells you that he has a history of severe congestive heart failure (CHF) and takes warfarin and furosemide daily. When he returns from CT, he seems slightly confused. Laboratory tests are pending. What is the best initial treatment?

**A.Administer a prothrombin complex concentrate (PCC).**

**B. Administer desmopressin (DDAVP) intravenously (IV).**

**C. Administer protamine sulfate IV.**

**D. Transfuse 2 units fresh frozen plasma.**

**E. Transfuse one bag of platelets.**

**Answer:** A. Prompt reversal of anticoagulation is important because approximately 5% of older adults is on warfarin, and others have pathologic coagulopathy. Specific considerations for reversing coagulation abnormalities in older trauma patients are the volume of reversal agents required and corresponding risk of fluid overload. PCCs require minimal volume compared with fresh-frozen plasma (FFP) but are costly. To reverse anticoagulation fully, 1 to 2 L of FFP may be required, presenting a limitation to rapid reversal in older patients at risk of fluid overload. Platelets, protamine, and DDAVP will not reverse the elevated international normalized ratio caused by warfarin.

**184.2.** Which of the following is the most common cervical spine fracture in geriatric trauma patients?

**A. Anterior wedge fracture**

**B. Compression fracture**

**C. Jefferson fracture**

**D. Spinoous process fracture**

**E. Type 2 odontoid fracture**

**Answer:** E. Because of the relative immobility of the cervical spine related to degenerative joint disease, the most common level of cervical spine injury in older adults is C1 to C3, a higher level than in younger patients. Among these upper cervical spine fractures, the most common is a type 2 odontoid fracture.

**184.3.** An 80-year-old woman presents after a motor vehicle accident (MVA). Her vital signs on arrival are as follows: heart rate of 112 beats/min, blood pressure of 88/65 mm Hg, respiratory rate of 18 breaths/min, and oxygen saturation measured by pulse oximetry (SpO₂) of 98%. The paramedic tells you that she has a history of CHF and takes furosemide daily. The primary survey does not reveal an obvious source of bleeding. Which of the following treatments is most appropriate to address the patient’s tachycardia and hypotension while searching for its cause?

**A. Give a bolus of 500 mL warmed normal saline.**

**B. Give 2 units of non–crossmatched type O blood.**

**C. Run an infusion of warm normal saline wide open.**

**D. Start dopamine at a low dose.**

**E. Type and match and wait for type-specific blood.**
Answer: A. The most prudent approach in the hypotensive older trauma patient is controlled boluses of warmed isotonic fluids, with frequent assessment of physical examination, vital signs, pulse oximetry, and urine output. Resuscitation with crystalloid may correct the patient’s hypotension, obviating the need for transfusion. The patient’s hypotension must be addressed immediately, and treatment should not be delayed for type-specific blood. Given her history of CHF, a wide open infusion of normal saline without an endpoint should not be administered. Vasopressors such as dopamine should not be given to any trauma patient, except in extreme circumstances. If the patient had an obvious source of hemorrhage, use of non–crossmatched type O blood would be appropriate as a first step, and starting with 1 unit would be appropriate.

184.4. A 76-year-old man presents after slipping and falling down several stairs at home. The patient is awake and alert and unsure if he lost consciousness after the fall. He complains of chest pain and has left chest wall tenderness and crepitance on examination. When you obtain a CT scan of his chest, it reveals four contiguous lateral rib fractures. The patient’s pain is only moderately relieved by 0.15 mg/kg of morphine sulfate IV. What is the most appropriate disposition for this patient?
A. Admission for pain control with IV opioids
B. Admission with anesthesia consultation for pain management
C. Continued observation in the ED for 6 additional hours of IV opioid management, followed by reassessment
D. Discharge home with oral opioids

Answer: B. Geriatric trauma patients with severe pain from rib fractures often require hospitalization to allow adequate and safe pain management, and those with flail segments or larger numbers of rib fractures may require intensive care unit admission. Pain control is of particular importance because rib fractures will lead to splinting and atelectasis and increase the risk of pneumonia. Analgesia can be administered with IV opioids via patient-controlled analgesia or an epidural analgesic. An anesthesia consultation is appropriate for the older rib fracture patient without pain relief from parenteral opioids.
CHAPTER 185
Drug Therapy in the Geriatric Patient
Asad E. Patanwala | Arthur B. Sanders

PRINCIPLES
There are approximately 20 million annual visits to US emergency departments (EDs) by older adults. This is expected to increase disproportionately compared to the general population based on estimates from the US census. Results of a survey of emergency clinicians indicated a lack of confidence in managing older ED patients and a desire for additional training. Drug therapy issues are particularly challenging in older adults because of altered pharmacokinetics and pharmacodynamics compared to younger adults. In addition, they take more medications, have more comorbidities, and are at increased risk for adverse drug effects because of the physiologic changes with aging than younger adults. As a result, medication selection and dosing need to be age-adapted for optimal patient outcomes. Also, compared to adults. As a result, medication selection and dosing need to be age-adapted for optimal patient outcomes. Also, compared to younger adults, there is less high-quality evidence for many drug therapy interventions in older adults. In those who are 80 years of age or older, there is even less evidence, making extrapolation from studies and evaluating risks versus benefits for pharmacologic options more difficult.

Most developed countries have adopted the chronologic age of 65 years to define the geriatric or older population. The United Nations does not have a standard definition, but generally uses the age of 60 years or older to refer to older persons. This categorization may be overly simplistic, and stratification, such as young old (60–69 years), middle old (70–79 years), and very old (≥80 years), is more suitable and medically useful. From a drug therapy perspective, physiologic age is more indicative of the therapeutic or toxicologic effect. However, there are no physiologic markers that define the aging process or that can be routinely used in clinical practice. Most studies evaluating medication use in older adults have used a cutoff value of 65 years, and this serves as basis for recommendations from the American Geriatrics Society. Thus, in this chapter, we refer to older adults as those with a chronologic age of 65 years or older. However, from an emergency clinician’s perspective, this is an arbitrary value for making drug therapy decisions. In addition to chronologic age alone, an overall assessment that incorporates organ function, comorbidity, functional status, and lifestyle is a better determinant of drug therapy selection and dosing. This should also be considered when interpreting recommendations for older adults, such as what is considered to be an inappropriate medication. This chapter reviews aspects of pharmacology for older adults and the clinical implications in emergency medicine.

Pharmacokinetics
The time course of drug exposure is a function of absorption, distribution, metabolism, and elimination. The drug effect is primarily determined by this exposure, which can be quantified by serum concentrations over time. It is assumed that increased exposure is also more likely to result in toxic medication effects. Thus, an understanding of pharmacokinetic changes in older adults is useful for determining risks of adverse drug reactions and helps guide medication selection and dosing.

The effect of changes in the absorption of drugs is important for orally ingested medications and can be affected by changes in gastric pH, gastric emptying, splanchnic blood flow, bowel motility, and absorptive capacity. For example, the increase in gastric pH associated with older adults can decrease the dissolution and absorption of medications that are weak bases. However, age-related changes in the gastrointestinal system can have a varied effect on drug absorption, leading to an increase or decrease in drug concentrations. As an example, decreased absorptive capacity coupled with decreased bowel motility can increase transit time, leading to a net neutral effect on drug exposure. Gastrointestinal and other comorbidities can have a greater effect on absorption than age alone. Given these considerations, it would be prudent in the ED to use the intravenous route for acute conditions, when rapid drug absorption is needed to achieve a therapeutic concentration.

Age-related changes in body composition have an effect on the distribution of drugs. There is an increase in total body fat and a decrease in relative skeletal muscle mass in older adults compared to young adults. This change in body composition accelerates between 60 to 75 years and then may start to decline. Lipophilic medications have a greater volume of distribution with increasing adiposity, whereas the opposite is true for hydrophilic medications. Opioid analgesics such as fentanyl and most sedatives (eg, benzodiazepines, propofol) are very lipophilic, so there is distribution and accumulation of the drug within adipose tissue. With prolonged use, this can lead to an increased duration of effect due to redistribution of drug from tissue to serum and central nervous system. Conversely, hydrophilic medications such as digoxin would require lower loading doses in older adults to achieve similar serum concentrations due to a smaller volume of distribution. This has the potential for drug toxicity if not dosed appropriately for age.

Most drugs require biotransformation into polar metabolites before final elimination. This primarily occurs in the liver via phase 2 metabolism by cytochrome P450 enzymes (oxidation) or phase 2 (conjugation, acetylation, sulfation) reactions. With advanced age, hepatic blood flow and mass may decrease by up to 40%, which reduces the delivery of medications to the liver and their subsequent metabolism. This decrease in first-pass metabolism improves drug bioavailability and efficacy and increases potential toxicity. Drugs with a high extraction ratio are more dependent on liver blood flow, and the decrease in liver metabolism with age has mainly been related to changes in phase 1 pathways. For example, morphine is a high-extraction ratio drug and would lead to greater drug exposure with decreased liver blood flow. Commonly used benzodiazepines in the ED also vary in their metabolic pathways. Midazolam undergoes phase 1 metabolism, and hepatic impairment would lead to drug accumulation, especially with repeated or prolonged use. Conversely, lorazepam undergoes conjugation and is preferred in patients...
with hepatic impairment. The effect of aging on phase 1 metabolism via CYP3A4 is controversial. This enzyme represents the metabolic pathway for most medications, and studies have shown no significant differences between younger and older populations.

Renal blood flow, renal mass, and the number of nephrons decrease with age, leading to a decrease in renal function. In a longitudinal study, renal function decreased by approximately 10% for each decade between 30 and 80 years of age. This decrease was independent of comorbid conditions, and was attributed to aging alone. Although this decline is likely to occur in most patients, up to one-third may have no decline, and some may have an increase in renal function. Kidney function is expressed as the glomerular filtration rate (GFR) and is routinely estimated by the Cockcroft-Gault equation. However, this equation may not accurately estimate the GFR, so the modification of diet and renal disease (MDRD) equation has been suggested as a more accurate estimation. Common equations used to calculate creatinine clearance and estimate GFR are in Box 185.1. Discordance in drug dosing recommendations, especially those with less musculature. For all older patients, some providers routinely round serum creatinine values less than 1 mg/dL up to 1 mg/dL to account for reduced muscle mass. However, this should be avoided in calculations because it has been shown to underestimate clearance.

In the ED, most medications are dosed just once or may be repeated a few times, and the possibility of drug accumulation, even with hepatic or renal impairment, is unlikely to be clinically meaningful. If, however, several doses of a medication are administered in the ED, especially when patients are boarded, drug toxicity or prolonged effects may be clinically important. In general, a start low and go slow approach is prudent in older patients. The risks versus benefits of drug therapies generally increase with age, suggesting that a lower dose approach is warranted. Pharmacokinetic changes in older adults are listed in Table 185.1.

Pharmacodynamics

At similar plasma concentrations, drugs may have altered effects in older adults, perhaps because of changes in the number and sensitivity of receptors, signal transduction, and reduction in homeostatic processes that help maintain equilibrium. Thus,
physiologic mechanisms that help restore function are attenuated, leading to an exaggerated or relatively unopposed pharmacologic effect. Pharmacodynamic changes in older adults that are most relevant to consider in the ED include those that pertain to the cardiovascular, central nervous, and coagulation systems. For example, there is a decreased response to both β-adrenergic receptor agonists and antagonists. Conversely, there is no age-related change in α₁-adrenergic receptor sensitivity. Calcium channel blockers cause a greater drop in blood pressure and heart rate in older adults compared to younger adults, so the risk for postural hypotension is higher in older adults. The diminished inotropic response to catecholamines contributes to this risk. In the ED, non–dihydropyridine calcium channel antagonists such as diltiazem or verapamil are commonly used for patients with supraventricular tachycardias. Lower doses are appropriate in older adults, especially when the patient has tenuous blood pressure.

There is increased sensitivity to benzodiazepines in older adults, and lower doses are needed to obtain similar sedative-hypnotic effects. This is because of changes in the structure, composition, and function of the γ-aminobutyric acid (GABA) receptor complex. Similarly, in one investigation, older patients required less propofol for the induction and maintenance of sedation during procedures in the ED. The dose required for induction was 0.5 mg/kg less than in the cohort of young adults. In older adults, it is more suitable to start with a 0.5- to 1-mg/kg bolus rather than the 1-mg/kg bolus that is recommended initially. Some studies have shown that older patients have increased sensitivity to opioids. Pharmacodynamic effects in these studies were measured in terms of electroencephalographic readings, which do not reliably indicate the presence of pain. However, the risk of adverse effects and interactions due to the use of concurrent medications is likely increased in older adults, suggesting that a cautious approach is appropriate when dosing opioids. There is an age-related decrease in dopamine content in the central nervous system, which predisposes patients who are given neuroleptics and other dopamine antagonists to extrapyramidal symptoms. Similarly, there is a decrease in acetylcholine synthesis in older adults, which increases the risk for anticholinergic neurotoxicity with commonly used antihistamines, antispasmodics, and antiparkinsonian agents.

Bleeding is a potentially life-threatening consequence of anticoagulants. Warfarin is the most commonly used oral anticoagulant, although, more recently, newer oral agents such as direct thrombin and factor Xa inhibitors have become available. At similar warfarin plasma concentrations, there is greater vitamin K inhibition in older adults. Thus, it is recommended that warfarin should be initiated at a daily dose of 5 mg or less for older adults, when indicated. In the ED, this may occur for patients discharged after a venous thromboembolism in conjunction with low-molecular-weight heparin as bridge therapy. Newer oral anticoagulants do not have pharmacodynamic considerations in older adults. However, dosing adjustments are needed based on renal function because they undergo renal elimination. The other primary anticoagulant used in the ED is intravenous heparin for acute coronary syndrome or venous thromboembolism. Patient age does not correlate with heparin dose requirements, so no heparin dose adjustments are required based on patient age.

**SPECIFIC DISORDERS**

**Polypharmacy and Drug Interactions**

The term *polypharmacy* is used to describe the use of multiple medications. There is no standard definition or consensus regarding the number of medications that serves as a cut point for this term. Many studies have considered five or more medications as defining polypharmacy. Older patients are particularly prone to polypharmacy because they have a greater number of comorbidities and conditions requiring treatment for medications. In one national estimate of community-residing older adults, close to one-third of the population took five or more medications, and approximately half also took over-the-counter medications and dietary supplements. Polypharmacy may result in adverse drug effects, drug interactions, and functional and cognitive impairment and lead to falls, resulting in injury. Approximately 10% of ED visits by older adults may be due to an adverse drug-related event.

An important consequence of polypharmacy is drug interactions, which occur more commonly in older adults. A drug interaction occurs when there is an alteration in the effect of a drug (object) due to the coadministration of another (precipitant). The alteration could be the increase in effect, leading to toxicity, or a decrease in effect, resulting in therapeutic failure. The mechanism of interaction could be pharmacokinetic, which is primarily due to the inhibition or induction of drug-metabolizing enzymes such as the cytochrome P450 system or alterations in drug transporter activity. Alternatively, the interaction could be pharmacodynamic, in which the change in effect is unrelated to pharmacokinetic mechanisms. This primarily occurs due to the pharmacologic effects of drugs, which may be additive or antagonistic. For example, the use of a benzodiazepine with an antibiotic that inhibits its metabolism would be a pharmacokinetic interaction, whereas the use of a benzodiazepine with an opioid, leading to additive central nervous system depression, would be a pharmacodynamic interaction.

There are thousands of possible drug-drug interactions, which increase exponentially with the number of medications that a patient is taking. Clinical decision support systems integrated with electronic medical records may provide a useful mechanism to reduce this risk. However, there are several challenges that need to be overcome in the ED setting so that providers than make the best possible decisions. The identification of an interaction is dependent on an accurate medication history, which is often difficult to obtain from older adults. Clinical decision support systems identify many drug interactions that are not clinically meaningful, leading to alert fatigue. It is estimated that providers override more than 80% of alerts, even when the interactions are significant. Furthermore, most interactions are based on preclinical studies during drug development, have a theoretical basis, and often lack high-level evidence. This leads to discrepancies in major drug information systems, and there is no standard classification to guide decisions.

A prudent approach is to focus on the most common drug interactions that have been known to result in patient harm and that may be most applicable to the emergency clinician. Single doses of drugs administered within the monitored setting of the ED are less likely to lead to harm than those prescribed on discharge and used for several days. Adverse events can be narrowed down to several interactions that resulted in hospitalization from hyperkalemia, hypotension, fractures, hypoglycemia, bleeding, and specific drug toxicities. The object drugs involved in these interactions should serve as important flags to alert prescribers when giving a new medication (Table 185.2). Most of these adverse events are seen to occur when new antibiotics are prescribed. Thus, antibiotics prescribed to patients need to be considered carefully for potential interactions, especially when patients are taking a medication such as one mentioned earlier. However, there are many other high-risk medications, such as antidepressants, neuroleptics, and antiepileptics, that are also known to have several drug-drug interactions. Ideally, consultation with a pharmacist is helpful in identifying and determining the risk of potential drug interactions and selecting appropriate alternatives, if necessary.

**Potentially Inappropriate Medications**

**Beers Criteria**

In 1991, Beers and colleagues developed explicit criteria defining inappropriate medication use in older adults. It is now known as the Beers criteria and is periodically updated by the American Geriatrics Society. At that time, it was observed that residents of skilled nursing facilities were prescribed eight medications on average; more than 50% of them received a psychoactive medication. The Beers criteria were applied to the older residents in nursing homes, representing the frailest of the population. Inappropriate medications were defined by an expert panel as those that should be avoided, except under unusual clinical circumstances. This was because of the lack of effectiveness, risks outweighing the benefits, or safer alternatives that were available. The criteria were developed so that they could be assessed from easily identifiable pharmacy records using minimal clinical data. This made it feasible for use for the quality improvement initiatives in skilled nursing facilities. The Beers criteria were subsequently updated so that they could be applied to all older patients, regardless of the place of residence. The most recent version from the American Geriatrics Society was developed by an 11-member panel with expertise in geriatric medicine, nursing, pharmacy, research, and quality measures. Each criterion for medication or class includes a quality of evidence rating and strength of recommendation, serving as a valuable resource for clinicians involved in the care of older adults.

Although important questions remain regarding the applicability of the Beers criteria to practice in the ED. For example, promethazine is considered to be an inappropriate medication for older adults because of its anticholinergic and central nervous system effects, and avoiding this agent was given a strong recommendation based on high-quality evidence by the expert panel.

*Propoxyphene is not included because it is no longer available.

Although the chronic effects of promethazine, such drug-related falls, constipation, and dry mouth, are not of particular concern in the ED, promethazine-induced confusion or sedation may be problematic in patients presenting with altered mental status. A safer alternative for nausea or vomiting in this latter circumstance would be a 5-HT3 receptor antagonist, such as ondansetron. However, even ondansetron has been associated with QTc interval prolongation, which could be concerning in older patients who are already taking QTc-prolonging medications, leading to a potentially severe drug interaction. These nuanced therapeutic decisions require emergency clinicians to consider patient-specific parameters and realize that a “one size fits all” approach may not be appropriate.

Medications provided on discharge create another challenge. Although a one-time dose in the ED is less likely to be problematic, medications prescribed on discharge must be given cautiously. Medications given to older patients on discharge should be prescribed for a limited period of time until follow-up by a primary care provider. In this setting, the Beers criteria may provide important guidance. For example, the Beers criteria expert panel has recommended that benzodiazepines should be avoided for the treatment of insomnia in older adults. This is because of the increased risk for cognitive impairment, delirium, falls, fractures, and motor vehicle collisions. Even short-term use of benzodiazepines after ED discharge could be associated with these adverse effects. In one randomized controlled trial, the use of a clinical decision support system in the ED was able to reduce the prescribing of potentially inappropriate medications in patients being discharged from the ED. Interestingly, the study targeted only a few medications, which accounted for 80% of the inappropriate medications prescribed on discharge. These medications, listed from the most to least commonly used, are in Table 185.3. Each institution should periodically evaluate trends in medications being prescribed and assessed for appropriateness because this can vary by center.

**STOPP and START Criteria**

In 2008, the STOPP (Screening Tool of Older People’s Potentially Inappropriate Prescriptions) and START (Screening Tool to Alert doctors to Right Treatment) tools were developed and validated. These screening tools built on the Beers criteria to overcome some of its limitations and further help clinicians determine when indicated medications should be prescribed. The Beers criteria accounts for only a small subset of medications that are prescribed...
inappropriately to older adults. In one national estimate of ED visits for adverse drug events in older adults, medications on the Beers criteria accounted for only 3.6% of visits. Approximately one-third of total visits were from only three medications—warfarin (17.3%), insulin (13.0%), and digoxin (3.2%). In addition, many of the medications in the Beers criteria may not be available in European countries or are seldom prescribed. In the ED setting, tools incorporating potentially inappropriate medications can be used to identify drug-related presentations, determine if medications are suitable to be used in the ED during acute illness, and guide medication prescribing on discharge. Even if a presentation is not drug-related, assessment in the ED is an opportunity to identify medications that may be problematic and lead to further admissions. In this regard, the STOPP screening tool was able to identify more patients than the Beers criteria for potentially inappropriate medications (35% vs. 25%) who presented to the ED of a university teaching hospital. The STOPP-related medications also contributed to twice the number of admissions (12% vs. 6%). The most recent version includes 80 STOPP and 34 START criteria.14 The top 10 criteria that identified the most patients with inappropriate medications are listed in Table 185.4.

Anticoagulation and Bleeding

Oral anticoagulation use is common for age-related conditions such as atrial fibrillation. Warfarin has been used for several decades but is less than ideal because it has a narrow therapeutic range. Routine laboratory monitoring is required, and numerous drug and food interactions lead to an unpredictable response, often resulting in bleeding. Of all drug-related presentations to the ED, warfarin-induced bleeding has been shown to be the most common in older adults.

More recently, newer oral anticoagulants have become available that do not require routine laboratory monitoring and have fewer drug interactions. These include a direct thrombin inhibitor (dabigatran) and factor Xa inhibitors (rivaroxaban, apixaban, edoxaban). High-quality randomized clinical trials of these new oral anticoagulants have shown them to be equivalent or superior to warfarin with regard to stroke prevention and bleeding occurrence for patients in atrial fibrillation.17-19 New agents account for over 60% of new anticoagulation prescriptions for atrial fibrillation.20 Postmarketing surveillance data are emerging suggesting that the new agents may be associated with a greater risk of bleeding, especially in those with renal impairment.11,20

One drawback of these agents is that they undergo renal elimination, and patients with severe renal impairment were excluded from major trials. Although dosing adjustment is recommended based on creatinine clearance, the fluctuating course of renal function in older adults during an acute illness may contribute to accumulation and bleeding. Furthermore, routine laboratory testing does not quantify the level of anticoagulation. For warfarin-induced bleeding, reversal is achieved when the international normalized ratio (INR) is less than 1.5. The new oral anticoagulants increase prothrombin time (PT), activated partial thromboplastin time (aPTT), and thrombin time, but these measures do not reliably estimate the level of anticoagulation and thus have limited ability to guide therapy. Laboratory parameters such as ecarin clotting time, diluted thrombin time, and chromogenic antifactor Xa assay may be potentially useful, but these tests are not widely available.21

Guidelines from the American College of Chest Physicians have recommended that four-factor prothrombin complex concentrate (PCC) is preferred over fresh-frozen plasma infusions for warfarin-induced bleeding, although this was given a weak recommendation grade based on low-level evidence.22 Four-factor PCC contains clotting factors II, VII, IX, and X. In older patients who are volume-restricted, the use of concentrated factor products is more appealing than fresh-frozen plasma because the usual volume of plasma needed for effective reversal can be 2 L, which can be problematic in frail older adults. The volume of four-factor PCC depends on the dose and product used, but is usually less than 100 mL. Vitamin K is also recommended in a dose of 5 to 10 mg to be given via the intravenous (IV) route for life-threatening bleeding.24 Although the onset of effect of IV vitamin K is not apparent for several hours, there will be a rebound increase in the INR during hospitalization if patients are not given vitamin K initially. This would require the provision of additional clotting factor, which increases the risk for thromboembolism, as well as drug cost to the institution.

No consensus recommendations or high-quality evidence is available for reversal of the new oral anticoagulants. There is some evidence to suggest that four-factor PCC is also effective for the factor Xa inhibitors but less effective for dabigatran.25 In dabigatran-induced bleeding, an activated four-factor PCC (FEIBA) that contains the same clotting factors but in activated form may be more effective.25 Dabigatran is also removed by dialysis because it has low protein binding, whereas factor Xa inhibitors are highly protein-bound and will not be removed by dialysis. Nonetheless, this may be impractical when rapid bleeding cessation is required. Because routine laboratory tests do not quantify the level of anticoagulation, clinical judgment is useful to determine if bleeding has stopped or if additional interventions are needed.

Neurologic Conditions

Altered mental status is a common chief complaint of older patients presenting to the ED. Although its cause may include a number of factors, medications need to be considered in the differential diagnosis for this presentation. Many of the medications on the Beers list are known to cause adverse neurologic effects. Medications with anticholinergic properties, in particular, are commonly associated with delirium. Avoidance of anticholinergic agents was given a strong recommendation based on moderate- to high-quality evidence by the American Geriatrics Society.26 There are numerous medications with anticholinergic effects, and toxicity is often due to a cumulative anticholinergic burden. Treatment

NSAID: Nonsteroidal antiinflammatory drug; STOPP (Screening Tool of Older People’s Potentially Inappropriate Prescriptions).
is supportive, along with discontinuation of the offending medications. Benzodiazepines may be used for agitated delirium after nonpharmacologic options have been exhausted. In a systematic review, there was moderate-quality evidence that benzodiazepine also contributed to delirium, and they should be used cautiously in the ED.27 When agitation is due to underlying psychiatric illness, neuroleptic agents such as haloperidol or an atypical antipsychotic may be used. Haloperidol has the least anticholinergic effect. However, doses given to older adults should be low (eg, ≤5 mg IM [intramuscular] or IV) to avoid the risk of extrapyramidal symptoms.28 Large dose of haloperidol given via the IV route have been associated with QTc interval prolongation, so monitoring of the electrocardiogram (ECG), if possible, is important, especially if repeated doses are needed.

There are also differences in the pharmacologic management of some key neurologic emergencies in older adults. In patients with community-acquired bacterial meningitis, the Infectious Disease Society of America has additional recommendations for older adults compared to young adults. In older adults, ampicillin is recommended in addition to the standard empirical regimen for coverage of Listeria monocytogenes. Thus, patients would receive a triple regimen of vancomycin, ceftriaxone, and ampicillin. However, the cutoff value for age is 50 years rather than the traditional age definitions for older adults. Similarly, there are differences in the eligibility criteria for thrombolytic therapy for ischemic stroke based on age. The most recent guidelines for stroke from the American Heart Association extend the time window for the provision of thrombolysis, from 3 to 4.5 hours after onset of symptoms.29 However, in addition to other criteria, patients older than 80 years are not eligible for this extended window. This is similar to the exclusion criteria of the trial on patients older than 80 years are not eligible for this extended use in older patients for severe pain in the ED is a two-step approach to suboptimal pain control. One strategy that has been successful is redosing every 1 to 2 hours is an unnecessarily long time and leads to repeated doses. The pharmacokinetic and pharmacodynamic characteristics of the drug must be fully used in older patients for severe pain in the ED is a two-step approach to suboptimal pain control. One strategy that has been successful is redosing every 1 to 2 hours, which is repeated in 15 minutes if the patient desires another dose when asked, “Do you want more pain medication?”30 However, previous opioid exposure needs to be considered to determine appropriate dosing. For example, in some older cancer patients with chronic opioid consumption, doses will likely need to be escalated for pain control.

Meperidine use should be avoided in older patients. It has a neurotoxic metabolite that accumulates with renal impairment common in these patients. Given the availability of alternative opioids, there is little reason to use this medication in the ED, and it is also listed on the Beers criteria. Ketorolac is a valuable alternative to opioids in the ED, and single doses have been shown to be as effective as opioids for pain related to certain indications, such as renal or gallbladder stones. However, it is a potent nonsteroidal antiinflammatory drug (NSAID) with the possibility of causing renal failure or gastrointestinal hemorrhage. This is less likely to occur with isolated doses in the ED setting. Nonetheless, a reduced dose is recommended for older adults (15 mg IV or 30 mg IM), which is half of the usual adult dose.32 This is done to minimize the possibility of these adverse effects.

Clinical Pharmacy Services

There are a growing number of institutions that have pharmacists who practice in the ED. The American Society of Health-System Pharmacists has published guidelines regarding pharmacy services to be provided to the ED, with one of the essential roles being monitoring and ensuring patient safety.33 In geriatric EDs, there is a great opportunity to integrate pharmacists, given the myriad drug therapy issues that can lead to suboptimal care.34 Older adults have more medications prescribed, which increases the risk for medication errors.35 Pharmacists are able to intercept these errors, preventing patient harm.36 Given the possibility of drug-induced admissions, pharmacy services can be used to identify medications that may have contributed to an ED presentation. However, resource constraints make it difficult for pharmacists to evaluate each geriatric patient, especially in EDs with large bed capacities.

Obtaining an accurate medication list is necessary for determining the cause of an adverse effect, but this often requires phone calls to multiple pharmacies and physicians’ offices. One option is the use of pharmacy technicians who are also able to perform this function with similar accuracy.37 Patients can also be referred to the pharmacist based on variables that have been associated with adverse drug events.38 One clinical decision rule was able to identify 96% of patients with adverse drug events by limiting referral of less than half of patients to a pharmacist so that a full review could be conducted. This decision rule is shown in Fig. 185.1.

Even if the presentation is unrelated to an adverse drug event, clinical pharmacists can be used to identify potentially inappropriate therapies that the patient is taking to minimize the possibility for readmissions. For example, it is possible that a patient may

**Analgesia**

In a national survey of US EDs, geriatric patients with pain-related complaints were less likely to receive any analgesics than young adults.30,31 The risk for poor pain management in older adults is multifactorial and increases with logistic constraints, such as ED crowding. Pain perception and susceptibility to adverse drug effects of analgesics is also different in older patients. Dosing of opioids should be cautious, and monitoring for respiratory depression needs to be vigilant. It is difficult to anticipate how much opioid would be required for pain control in the ED. Instead of large single doses, a lower dose with titration consistent with pharmacokinetic and pharmacodynamic characteristics of the opioid is ideal. For example, morphine and hydromorphone have their peak analgesic effect at approximately 15 minutes. Thus, redosing every 1 to 2 hours is an unnecessarily long time and leads to suboptimal pain control. One strategy that has been successfully used in older patients for severe pain in the ED is a two-step hydromorphone protocol.32 Patients are given 0.5 mg IV hydromorphone, which is repeated in 15 minutes if the patient desires another dose when asked, “Do you want more pain medication?”33 However, previous opioid exposure needs to be considered to determine appropriate dosing. For example, in some older cancer patients with chronic opioid consumption, doses will likely need to be escalated for pain control.

Meperidine use should be avoided in older patients. It has a neurotoxic metabolite that accumulates with renal impairment common in these patients. Given the availability of alternative opioids, there is little reason to use this medication in the ED, and it is also listed on the Beers criteria. Ketorolac is a valuable alternative to opioids in the ED, and single doses have been shown to be as effective as opioids for pain related to certain indications, such as renal or gallbladder stones. However, it is a potent nonsteroidal antiinflammatory drug (NSAID) with the possibility of causing renal failure or gastrointestinal hemorrhage. This is less likely to occur with isolated doses in the ED setting. Nonetheless, a reduced dose is recommended for older adults (15 mg IV or 30 mg IM), which is half of the usual adult dose.32 This is done to minimize the possibility of these adverse effects.

**Clinical Pharmacy Services**

There are a growing number of institutions that have pharmacists who practice in the ED. The American Society of Health-System Pharmacists has published guidelines regarding pharmacy services to be provided to the ED, with one of the essential roles being monitoring and ensuring patient safety.33 In geriatric EDs, there is a great opportunity to integrate pharmacists, given the myriad drug therapy issues that can lead to suboptimal care.34 Older adults have more medications prescribed, which increases the risk for medication errors.35 Pharmacists are able to intercept these errors, preventing patient harm.36 Given the possibility of drug-induced admissions, pharmacy services can be used to identify medications that may have contributed to an ED presentation. However, resource constraints make it difficult for pharmacists to evaluate each geriatric patient, especially in EDs with large bed capacities.

Obtaining an accurate medication list is necessary for determining the cause of an adverse effect, but this often requires phone calls to multiple pharmacies and physicians’ offices. One option is the use of pharmacy technicians who are also able to perform this function with similar accuracy.37 Patients can also be referred to the pharmacist based on variables that have been associated with adverse drug events.38 One clinical decision rule was able to identify 96% of patients with adverse drug events by limiting referral of less than half of patients to a pharmacist so that a full review could be conducted. This decision rule is shown in Fig. 185.1.

Even if the presentation is unrelated to an adverse drug event, clinical pharmacists can be used to identify potentially inappropriate therapies that the patient is taking to minimize the possibility for readmissions. For example, it is possible that a patient may

---

**Fig. 185.1.** Decision rule to identify adverse drug events. *Triage acuity* was determined by the Canadian Triage Acuity Scale. A score of 1 to 3 was considered high acuity. This includes patients with at least urgent or emergent conditions who need to be seen by a physician within 30 minutes.
Those with a chronologic age of 65 years or older are commonly referred to as older adults (or the elderly), but physiologic age is more indicative of a drug’s therapeutic or toxicologic effect. Besides age, overall patient assessment should include organ function, comorbidity, and functional status to guide drug dosing. Pharmacokinetic and pharmacodynamic changes that occur with age need to be considered to optimize drug dosing and minimize toxicity in older adults. In most cases, a start low, go slow approach is recommended. Multiple or repeated dosing is more likely to lead to drug accumulation compared to single doses in the ED. Polypharmacy is common in older adults, predisposing them to adverse drug effects, drug interactions, and functional and cognitive impairment. Some of these medications do not have legitimate indications or may be inappropriate. There are published lists of potentially inappropriate medications, such as the Beers list and the STOPP and START criteria, but there are limited studies to enable extrapolation to the ED setting. Of all drug-related presentations to the ED, warfarin-induced bleeding has been shown to be the most common in older adults. However, the use of newer oral anticoagulants, such as direct thrombin inhibitors and factor Xa inhibitors, has been increasing. These newer agents undergo renal elimination; thus, drug accumulation is a concern in older adults. Older adults often present to the ED with altered mental status. Drug-related causes such as anticholinergic medication burden should be considered in the differential diagnosis. Geriatric patients with pain-related complaints are less likely to receive analgesics in the ED compared to younger adults, placing them at risk for poor pain control. Dosing of opioids should be cautious, with frequent monitoring and titration. Given the availability of alternative opioids, the use of meperidine should be avoided. A growing number of institutions have pharmacists practicing in the ED. In geriatric EDs, there is a great opportunity to integrate and consult with pharmacists, given the myriad drug therapy issues that can lead to suboptimal care.

CHAPTER 185: QUESTIONS & ANSWERS

185.1. Which of the following pharmacokinetic change in older adults is associated with increased plasma concentration of drug? A. Decrease in absorptive capacity in an orally administered medication B. Decreased glomerular filtration rate in a renally eliminated medication C. Increase in gastric pH in a medication that is a weak base D. Increased liver blood flow in a high–extraction ratio medication E. Increased total body water in hydrophilic medications Answer: B. Decrease in glomerular filtration rate is common with age. This leads to decreased elimination and increased plasma concentration of a drug. All other options listed would lead to decreased plasma drug concentrations. Liver blood flow, glomerular filtration rate, total body water, and absorptive capacity decrease with age. However, gastric pH increases.

185.2. Which of the following is the most appropriate strategy for analgesic provision in an older patient with renal insufficiency and severe abdominal pain in the emergency department? A. Hydromorphone 0.5 mg IV, followed by the same dose in 15 minutes, if needed B. Ketorolac, 30 mg IV qid C. Meperidine, 50 µg IV every 2 hours D. Morphine, 4 mg IV every 2 hours E. Oxycodone/acetaminophen, 5/235 mg orally every 2–4 hours Answer: A. One strategy that has been used successfully in older adults is a two-step hydromorphone protocol. Patients are given 0.5 mg IV hydromorphone, which is repeated in 15 minutes if the patient desires another dose when asked, “Do you want more pain medication?” Hydromorphone does not have active metabolites that would accumulate with renal insufficiency, so it would be an appropriate option for severe pain. Ketorolac should be avoided.
in older adults with renal insufficiency because the inhibition of prostaglandins can decrease renal blood flow. Meperidine use is no longer recommended because of a neurotoxic metabolite and accumulation in renal insufficiency. Morphine has an active metabolite that also accumulates in renal insufficiency. Oxycodone-acetaminophen given orally is not appropriate for severe acute pain due to delayed onset of effect. Bioavailability of oral medications may further be delayed in older adults.

185.3. Which of the following statements is true regarding reversal of anticoagulation in older adults who are bleeding?

A. Intravenous vitamin K can be avoided if factor concentrates are provided.
B. Dabigatran is not removed by hemodialysis because of high protein binding.
C. Prothrombin complex concentrate is preferred to plasma transfusion.
D. Plasma transfusion is preferred to prothrombin complex concentrate.
E. Factor Xa inhibitors can be removed by hemodialysis because of low protein binding.

**Answer:** C. Prothrombin complex concentrate has a lower volume of administration, which is beneficial for volume-restricted older adults. It is preferred to plasma transfusion based on low-level evidence. Intravenous vitamin K should be given with factor concentrates to sustain the reversal of anticoagulation. Dabigatran has low protein binding and thus can be removed by prolonged hemodialysis, but this is often not practical when emergent bleeding cessation is required. Factor Xa inhibitors are highly protein-bound and are not removed by hemodialysis.

185.4. Which of the following medications prescribed on discharge is most likely to interact in an older patient taking warfarin?

A. Albuterol inhaler for asthma
B. Ciprofloxacin for urinary tract infection
C. Insulin NPH for hyperglycemia
D. Oxycodone for fracture pain
E. Promethazine for nausea

**Answer:** B. Studies of harmful drug interactions in older adults have shown that the initiation of antibiotics in patients taking warfarin can lead to bleeding. Ciprofloxacin can lead to an elevation in the international normalized ratio (INR) due to disruption of vitamin K synthesis in patients taking warfarin. Thus, more frequent monitoring is required when ciprofloxacin is initiated. The other options listed do not interact with warfarin. However, oxycodone and promethazine can be harmful because of central nervous system effects, potentially leading to falls.

185.5. Which of the following statements is true regarding neurologic emergencies in older adults?

A. Ampicillin is added for the treatment of bacterial meningitis for additional coverage against Enterococcus faecalis.
B. Anticholinergic medication use is not associated with delirium.
C. Haloperidol, 10 mg IV, is recommended for acute agitation due to underlying psychiatric illness.
D. In patients with ischemic stroke who are older than 80 years, alteplase may be administered up to 4.5 hours after the onset of symptoms, according to guidelines.
E. Large doses of haloperidol given via the IV route have been associated with QTc interval prolongation.

**Answer:** E. There is a US Food and Drug Administration (FDA) black box warning regarding the use of haloperidol and QTc interval prolongation. This risk is increased with large doses given intravenously. Polypharmacy in older adults also puts them at risk for drug interactions due to concomitant QTc-prolonging agents. Doses of haloperidol should be less than 5 mg in most older adults. Ampicillin is added for bacterial meningitis to cover Listeria monocytogenes. Although recent evidence has extended the 3-hour time window to 4.5 hours for receiving alteplase after the onset of stroke in a small subset of patients, those older than 80 years are not eligible, according to guidelines. Anticholinergic medications are known to be associated with delirium and sedation.
Elder abuse and neglect encompasses a wide variety of behaviors perpetrated upon an older person that can have serious medical and social consequences. There are no universally accepted definitions of elder abuse and neglect, but most include the concept, initially developed by a 2002 National Academy of Sciences panel, that elder mistreatment involves a trusting relationship between an older person and another individual in which the trust has been violated in some way. The definition that best captures current understanding is that which was developed for the 2014 Elder Justice Roadmap, a report prepared by a large, multidisciplinary team of stakeholders inside and outside the United States government, defining elder abuse as:

*Physical, sexual, or psychological abuse, as well as neglect, abandonment, and financial exploitation of an older person by another person or entity that occurs in any setting (eg, home, community, or facility), either in a relationship where there is an expectation of trust and/or when an older person is targeted based on age or disability.*

This elder mistreatment may include physical abuse, sexual abuse, neglect, emotional/psychological abuse, abandonment, financial/material exploitation, and self-neglect (Table 186.1). Many victims may suffer concurrently from multiple types of abuse.

### Epidemiology and Scope of the Problem

Elder abuse and neglect is common and can have a profound impact. Recent prevalence studies suggest that as many as 10% of community dwelling older adults experience some form of abuse, neglect, or exploitation each year.\(^1\)\(^-\)\(^3\) Multiple smaller studies suggest that nearly 50% of dementia sufferers are victims of mistreatment by caregivers.\(^4\)\(^-\)\(^5\) In prevalence studies, psychological/emotional abuse (4.6% to 12.9%), financial mistreatment (3.5% to 6.6%), and neglect (5.1% to 5.4%) are most commonly reported, with physical mistreatment (0.2% to 2.1%) and sexual abuse (0.3% to 0.6%) less frequently reported.\(^1\)\(^-\)\(^3\)\(^5\) In a study of substantiated elder abuse cases from the United States, 58% involved neglect, 15% financial exploitation, 15% emotional abuse, 11% physical abuse, and 1% sexual abuse.\(^3\)

Elder abuse is strongly associated with adverse health outcomes, including increased emergency department (ED) usage, hospitalization, dementia, depression, nursing home placement, and dramatically increased mortality. The annual direct medical costs in the United States associated with violent injuries to older adults are estimated at $5.3 billion. This large disease burden and cost are likely to increase significantly due to anticipated geriatric population growth, particularly among the “oldest old” aged 85 years or older, who are the fastest growing segment of the adult population and are particularly vulnerable to the effects of abuse and neglect.

Despite its frequency and potential for significant harm, elder abuse and neglect is under-recognized and under-reported, with many sufferers enduring it for years before discovery. Studies suggest that as few as 1 in 24 cases of elder abuse is reported to the authorities, and much of the associated morbidity and mortality is likely due to this delay in identification and intervention.\(^1\)\(^,\)\(^2\)

Many factors likely contribute to the occurrence of elder abuse and neglect. Several theories have been proposed to describe the underlying causes of elder mistreatment (Table 186.2). Although none of these theories alone fully explains this complex phenomenon, each offers insights into aspects of elder mistreatment and thus suggests potential targets for interventions to manage confirmed cases.

Recent research has focused on identifying risk factors for becoming a victim or perpetrator of elder abuse and neglect. Findings have been inconsistent and difficult to interpret, with some studies suggesting that older age (>80 years old) increases risk of victimization, whereas others correlate higher risk with younger age (<70 years old). This inconsistency is likely partly due to the significant methodological limitations of current studies and the heterogeneity of elder mistreatment cases. Despite these limitations, potential risk factors for becoming a victim or perpetrator based on existing evidence are described in Box 186.1. Many cases of elder mistreatment occur in the absence of risk factors, however, and the phenomenon crosses ethnic and socioeconomic boundaries, so emergency clinicians should be vigilant in assessing older adult patients.

### Identifying Elder Abuse and Neglect in the Emergency Department

The ED visit is an important and often underutilized opportunity to identify elder abuse or neglect, which may otherwise remain undiscovered. For many older adults, assessment by health care providers is their only contact outside the family. Emergency clinicians, therefore, have a unique opportunity to diagnose and report suspected elder abuse and initiate further evaluation by elder abuse teams and adult protective services (APS). Emergency clinicians, who typically manage acute injuries and illnesses, are particularly well-positioned to identify abuse. Despite this, only 1.4% of cases reported to APS come from emergency clinicians, and, in a survey of APS workers, of 17 occupational groups, physicians were among the least helpful in reporting abuse. Several reasons exist for this missed opportunity, including lack of awareness, inadequate training, insufficient information about available resources, lack of time to conduct a thorough evaluation.

for abuse, misinterpretation of the sequelae of elder abuse or neglect as the result of accidental injury or illness, concern about involvement in the legal system, and desire to protect clinician-patient confidentiality. Despite these challenges, it is critical that emergency clinicians explore the potential for elder abuse and neglect when assessing older adult patients.

CLINICAL FEATURES

Screening

The American College of Emergency Physicians and American Medical Association have recommended that all EDs and all
and family dynamics that may inform the ED assessment. Emergency department (ED), may have critical information about the home situation who typically have the opportunity to evaluate patients in their younger patients, paramedics and emergency medical technicians, times more likely to be brought in by ambulance to the ED than home, the availability of food, medications, heat, and sanitation, about unusual family interactions, cleanliness and upkeep of the home. mistreatment are listed in Box 186.3. Because older adults are four times more likely to be brought in by ambulance to the ED than emergency clinicians and are an accreditation requirement for hospitals. In the United States, the Joint Commission requires that EDs screen all patients for abuse or neglect. Several screening tools have been devised to aid in the detection of elder abuse, but they are not applicable to all clinical environments, and few have been validated in primary care settings. The Elder Abuse Suspicion Index (EASI) is a short screening instrument that is easy to use in the ED and has been validated for cognitively intact patients in family practice and ambulatory care settings. It is detailed in Box 186.2.

Medical History

Obtaining an accurate and thorough medical history is critical to effectively assess for elder mistreatment, although this may be challenging for ED staff. Potential historical indicators of elder mistreatment are listed in Box 186.3. Because older adults are four times more likely to be brought in by ambulance to the ED than younger patients, paramedics and emergency medical technicians, who typically have the opportunity to evaluate patients in their home, may have critical information about the home situation and family dynamics that may inform the ED assessment. Emergency clinicians should seek out prehospital personnel and inquire about unusual family interactions, cleanliness and upkeep of the home, the availability of food, medications, heat, and sanitation, and the safety of the home for the older patient. When initially assessing an older adult with a caregiver present, the emergency clinician should carefully observe their interaction, identifying any clues of a strained relationship. History should be taken from the patient in an private setting as possible, without caregivers or family present. If a translator is needed, someone other than a family member or the caregiver should be used. The assessment for elder mistreatment should be incorporated into the routine evaluation. The emergency clinician may ask in detail about the reason for the ED visit and then inquire about the patient’s health in general, focusing on the safety of the home environment and any need for support or assistance. A clinician may follow up about specific types of abuse suspected as appropriate. Box 186.4 suggests potential questions to screen for abuse. If the older adult is presenting with any injury, the emergency clinician should question the patient about how the injury occurred, including directed questions regarding whether anyone has hit, punched, pushed, tripped, or kicked the patient. Unfortunately, obtaining a reliable history from victims of elder abuse and neglect is often difficult. Many older adults have advanced dementia or cognitive impairment that prevents them

**Potential Risk Factors for Elder Abuse**

**FOR BECOMING A VICTIM**
- Functional dependence or disability
- Poor physical health
- Cognitive impairment/dementia
- Poor mental health
- Low income/socioeconomic status
- Social isolation/low social support
- Previous history of family violence
- Previous traumatic event exposure
- Substance abuse

**FOR BECOMING A PERPETRATOR**
- Mental illness
- Substance abuse
- Caregiver stress
- Previous history of family violence
- Financial dependence on older adult

**Elder Abuse Suspicion Index**

Questions 1 through 5 are answered by the patient. Question 6 is answered by the physician. The patient can answer “yes,” “no,” or “unsure.” A response of “yes” on one or more of questions 2 through 6 should prompt concern for abuse or neglect.

1. Have you relied on people for any of the following: bathing, dressing, shopping, banking, or meals?
2. Has anyone prevented you from getting food, clothes, medication, glasses, hearing aids, or medical care or from being with people you wanted to be with?
3. Have you been upset because someone talked to you in a way that made you feel shamed or threatened?
4. Has anyone tried to force you to sign papers or to use your money against your will?
5. Has anyone made you afraid, touched you in ways that you did not want, or hurt you physically?
6. Doctor: Elder abuse may be associated with findings such as poor eye contact, withdrawn nature, malnourishment, hygiene issues, cuts, bruises, inappropriate clothing, or medication compliance issues. Did you notice any of these today or in the last 12 months?

**Indicators From the Medical History of Possible Elder Mistreatment**

- Poor living conditions according to paramedics or others
- Unexplained injuries
- Past history of frequent injuries
- Delay between onset of medical illness or injury and seeking of medical attention
- Recurrent visits to the ED for similar injuries
- Using multiple physicians and EDs for care rather than one primary care physician (“doctor hopping or shopping”)
- Noncompliance with medications, appointments, or physician directions
- Patient or caregiver reluctant to answer questions
- Strained patient/caregiver interaction
- Inconsistent history of injury mechanism between the patient and caregiver
- Elderly patient referred to as “accident prone”
- Caregiver not able to give details of the patient’s medical history or routine medications
- Caregiver answers the questions regarding the patient
- Abandonment of the patient in the ED by the caregiver

ED, Emergency department.
cognitive impairment can often relate how an injury occurred.7 In these cases, the patient, because recent research suggests that older adults with cognitive impairment may have difficulty providing an accurate medical history. Even in these cases, it is often useful. It may reveal important discrepancies from the information provided by the provider. For example, it may be neglecting them. The emergency clinician should be careful to conduct this interview in a nonthreatening and nonjudgmental manner, because the goal is not to accuse the caregiver but rather to obtain information. Verbal expressions of sympathy, rather than an accusation, may promote information sharing. Questions should also explore whether any important changes or recent stresses have occurred in the household, whether the caregiver feels that the patient is a burden, the caregiver’s other dependents and responsibilities, and whether any respite services or other home help services have been made available.

Physical Examination

Many clues to the presence of elder physical abuse, sexual abuse, or neglect may be present on physical examination (Box 186.5 and Figs. 186.1 to 186.11), and emergency clinicians should evaluate older adults thoroughly and carefully. When an older adult presents with an acute injury (such as, a fall), consider whether the reported mechanism is consistent with the injuries suffered. Particular attention should be given to a full skin examination, which may reveal important findings that might otherwise be missed. Unfortunately, it can be difficult to distinguish between elder abuse or neglect and the sequelae of accidental trauma and acute or chronic illness. This is made more challenging by the

normal physiologic changes that occur with aging, such as osteopenia, thinning of the skin, and easy bruising. Emergency clinicians should, therefore, consider elder mistreatment in the differential diagnosis of many conditions that occur frequently in older adults. Geriatric patients with multiple suspicious clinical findings may be more likely to be victims of elder abuse or neglect than those with isolated findings.

**DIFFERENTIAL DIAGNOSES**

Though under-recognized, sexual assault of older adults occurs and should be considered by emergency clinicians. If sexual abuse is suspected or reported and a genitourinary examination reveals evidence of trauma or vaginal bleeding, emergency clinicians should conduct a complete sexual assault examination, as in cases with younger victims. This evaluation should include evidence...
collection by a forensic examiner with appropriate training and expertise.

Recent research has begun to systematically explore whether injury patterns exist that are pathognomonic for elder mistreatment (analogous to findings in child abuse, such as shaken baby syndrome and bucket-handle metaphyseal fracture). One recent study compared bruises in 67 elder abuse victims to older adults with accidental trauma, finding that victims of elder abuse had bruises that were more often large (>5 cm) and found on the face, lateral right arm, or posterior torso. A literature review identified 839 reported cases of physical elder abuse and found that two-thirds of injuries that occur in elder abuse are to the upper extremity and maxillofacial region. More systematic research into clinical features distinguishing between elder abuse and accidental injury or illness is critically needed.

**DIAGNOSTIC TESTING**

No laboratory tests exist to definitively detect abuse, but medical and laboratory findings may suggest elder mistreatment. These include malnutrition, dehydration, anemia, hypothermia/hyperthermia, and rhabdomyolysis. In addition, serum or urine drug levels may be useful, because undetectable levels of prescribed medications may indicate that a caregiver is intentionally or neglectfully withholding. Perpetrators may divert controlled substances, such as narcotic pain medications, for their own use or to sell. Elevated serum levels of prescription medications may suggest intentional or unintentional overdose, and the presence of toxins or drugs that have not been prescribed may indicate poisoning. Platelet count and coagulation studies may helpful in ruling out a medical etiology for unexplained or abnormal bruising.

**MANAGEMENT**

When elder abuse or neglect is identified or suspected, management should include treating acute medical and psychological
issues, ensuring patient safety, and proper reporting to the authorities.

Traumatic injuries and metabolic abnormalities including dehydration are common and should be stabilized and treated. Management of worsening chronic medical conditions may be required due to an abuser’s failure to provide appropriate care. In some circumstances, hospitalization may be necessary to provide extended treatment and observation.

If a mistreatment victim is in immediate danger, the patient should be prevented from having any contact with the suspected abuser. In some cases, the suspected abuser may be the patient’s official health care proxy. In extreme cases, this may require security watch for the patient and even having the abuser removed from the ED and law enforcement, hospital social workers and administrators should be alerted. Alternate living arrangements may need to be arranged for the patient, with a reliable family member or friend or in an appropriate emergency shelter. If none of these options are available, the patient may require hospital admission to ensure safety.

If the patient refuses intervention, the emergency clinician must determine whether the patient has the capacity to make this decision. A psychiatric consultation may be helpful. The wishes of an older adult with decision-making capacity who desires to return to an abusive situation must be respected, as in cases of intimate partner violence among younger adults. If possible, the emergency clinician should educate the patient about the potential for escalation in violence and abuse and provide appropriate referral materials for future use.

In suspected cases of elder mistreatment without an imminent threat to a patient’s safety, interventions are individualized. If the patient wants to return home and may be safely discharged, the emergency clinician should coordinate with the patient’s primary care physician to ensure an appropriate longitudinal follow-up plan. Social workers may be able to offer resources to both the patient and the caregiver, including senior centers, medical transportation services, Meals-on-Wheels, adult day care, respite care, and substance abuse treatment. Ideally, elder mistreatment cases are managed in the community by a multidisciplinary team and involve home visits and advocacy.

**Documentation**

Accurate and thorough documentation of the history and physical examination findings is critical in cases of suspected elder mistreatment. The emergency clinician should document the history in the patient’s own words if possible. Pertinent social history (eg, patient’s functional status, caregiver’s relationship to patient, living arrangements) should be included. The clinician should describe the patient’s general appearance, including signs of potential neglect, such as a soiled diaper, inappropriate or dirty clothing, or dirt under nails. Injuries of any type (eg, fractures, lacerations, and contusions) should be described, including their number, size, location, and stage of healing and comment about whether the injuries are consistent with the reported mechanism. If possible, photographs of all injuries should be obtained and added to the medical record. The results of laboratory investigations and imaging studies should also be recorded. Careful documentation of interventions, follow-up plans, and referrals should be made. In cases of suspected elder abuse that result in legal action, thorough documentation may be critical to ensure justice for the victim.

**Reporting Requirements**

Although all states in the United States have laws on reporting and investigation of elder abuse, the definitions of elder abuse and requirements of the laws vary. In most states, emergency clinicians
are mandated to file a report if they know or reasonably suspect that elder abuse has occurred. Many of the states with mandatory reporting requirements grant immunity to emergency clinicians who report. Most state laws also have a penalty for failure to report, which may include a fine, a prison sentence, or both. A clinician does not have to confirm that abuse or neglect has occurred to report; a legitimate suspicion is all that is required to prompt a more thorough investigation. In most states, APS is the agency responsible for receiving and investigating all reports of suspected elder abuse. In some states, emergency clinicians are also required to report to law enforcement. Emergency clinicians should become familiar with state laws pertaining to elder abuse and their duty to report in the state in which they practice. The Administration of Aging’s National Center on Elder Abuse website (https://ncea.acl.gov) is the most comprehensive online resource available on elder abuse and neglect.

**SPECIFIC DISORDERS**

**Elder Mistreatment in Institutions**

Residents of skilled nursing facilities account for over 2.2 million ED visits annually in the United States. This currently represents 11% of all visits by patients aged 65 years old or older and is rising. Elder abuse and neglect may also occur in these institutions. Emergency clinicians may play an important role in identifying this elder mistreatment, because each nursing home resident presents to the ED an average of 1.6 times every year.

Over the last several decades, increased regulatory scrutiny has improved care and reduced staff mistreatment of older adults in skilled nursing facilities. In the 1970s, the Long-Term Care Ombudsman Program was created nationally to monitor nursing homes and to investigate cases of suspected elder abuse and resident complaints. Mandatory criminal background checks of all employees were established. The Nursing Home Reform Act in 1986 included provisions for residents’ rights, which incorporated minimizing the use of restraints. The current prevalence of elder mistreatment in institutions is not well known, but research suggests it may still be common. In a recent study, 24% of family members of nursing home residents reported at least one incident of physical abuse against their elderly family member by nursing home staff. Forensic analysis of 2400 deaths in nursing homes found 50 suspected cases of fatal elder abuse or neglect. Poor working conditions, low wages, low staff-to-patient ratio, and inadequate training or supervision may increase the likelihood of nursing home staff members mistreating residents.

In addition to staff abuse and neglect of nursing home residents, resident-to-resident elder mistreatment has been recently identified as important problem. The prevalence of this phenomenon is unknown, but, given that dementia and associated behavioral disturbance in long-term care facilities is high, aggressive behavior can occur between residents. Additional research is needed to improve recognition of this type of elder mistreatment. When abuse or neglect of any kind in patients from nursing homes is identified or suspected, emergency clinicians should report to APS or the long-term care ombudsman in their state (www.ltcombudsman.org) for further investigation.

**Self-Neglect**

Self-neglect includes behaviors in which an older adult threatens his/her own health or safety by failing to perform or refusing assistance with essential self-care. This may include malnutrition due to not eating, failure to take necessary medications, inattention to personal hygiene, hoarding, and not maintaining safe home environment. Often, patients with self-neglect suffer from an underlying mental disorder, including mild cognitive impairment, depression, psychosis, or substance abuse disorders that prevents them from understanding that their health and safety are at risk and that they need to seek assistance. Self-neglect is associated with increased mortality.

Emergency clinicians frequently encounter patients who suffer from self-neglect, because it is the most common form of elder mistreatment reported to social services, with reports rising. As with other types of elder mistreatment, recognition by an emergency clinician of this condition is critical, because many of these older adults have virtually no other contact outside the home. Prehospital personnel, who may note an empty refrigerator, expired pill bottles, or vermin infestation, are critical in identifying patients at risk.

**DISPOSITION**

Although evidence-based strategies for intervention have not been established, a reasonable approach for an emergency clinician includes laboratory assessment for metabolic and nutritional abnormalities and social work evaluation to offer resources and services. Many of these patients will require hospital admission, because it will be impossible to establish a safe discharge plan. If the patient refuses hospitalization, as is common, the clinician must determine whether the patient has the capacity to make this decision. A formal decision-making capacity evaluation by a psychiatrist may be helpful. In a patient with decision-making capacity, it is important to provide, whenever possible, education and resources as the patient leaves the ED. Also, when possible, contacting the patient’s primary care physician and family members or friends who can check on the patient may help ensure safety.

**KEY CONCEPTS**

- Elder mistreatment, which includes physical abuse, sexual abuse, neglect, emotional/psychological abuse, abandonment, financial/material exploitation, and self-neglect, is common and may have serious medical and social consequences.
- Elder mistreatment is significantly under-recognized by emergency clinicians and under-reported to the authorities.
- Signs suggestive of potential elder abuse and neglect that should be recognized by emergency clinicians may exist in the medical history, physical examination, and medical/laboratory markers.
- Emergency clinicians should be vigilant in assessing for the possibility of elder abuse or neglect and routinely ask elderly patients about mistreatment, even in the absence of signs and symptoms.
- Emergency clinicians should hospitalized elderly patients who are in immediate danger or implement a care plan that prevents them from having any contact with the suspected abuser(s).
- Emergency clinicians must respect the wishes of an older adult with decision-making capacity who refuses interventions and desires to return to an abusive situation. If possible, the clinician should provide education and give information about available resources.
- The wishes of a competent elderly patient are required to be respected, even if the patient is not willing to accept interventions.
- Emergency clinician should always strongly consider reporting known or suspected cases of elder abuse or neglect to the authorities, and, in most states, emergency clinicians are mandated reporters.
REFERENCES

CHAPTER 186: QUESTIONS & ANSWERS

186.1. A 70-year-old man who lives alone but has 12 hours per day of a home attendant is brought to the emergency department (ED) by his daughter, who found him in his caregiver’s home with severe bruising. On examination, he had multiple bruises at varying stages of healing on the chest and arms, as well as a possible pattern injury—a bruise in the shape of a rectangle—across his left chest. What should you do?
A. Ask the daughter to make a report to adult protective services (APS), because she is the one who found him.
B. Contact the long-term care ombudsman.
C. Do not make a report because he has a long history of falls.
D. File a report with APS or law enforcement if your suspicion for abuse is high.
E. Interrogate the caregiver. If she denies abuse, do not report it.

Answer: D. The patient should be asked questions in a nonthreatening atmosphere, separate from the caregiver. If a clinician still has high suspicion, a report should be made to APS and/or law enforcement. The physician has the obligation to make the report. The long-term care ombudsman should be contacted only if the suspected abuse occurs in a facility, such as a nursing home.

186.2. A 72-year-old female is brought to the emergency department (ED) by paramedics for “not eating for 5 days” according to her family. The paramedics noted that she was covered in urine and feces and that the house was filthy, and she was found lying on the floor. On examination, she is noted to have a stage 4 pressure ulcer on her sacrum, which appears infected. Which of the following concerning for neglect?
A. Delay in seeking care
B. Evidence of dehydration
C. Poor hygiene
D. Pressure ulcer
E. All of the above

Answer: E. All of the above signs are potential markers for neglect.

186.3. A 69-year-old man with dementia presents to the emergency department (ED) with pneumonia and delirium. He is very confused, and his cognition is markedly worse than his baseline. You are called to the bedside because his adult daughter is at the bedside asking him to sign a legal form giving her the deed to his house. What should you do?
A. Perform an assessment of cognition and capacity and document it on the chart.
B. Request that the hospital lawyer and notary be present.
C. Tell her that there must be two witnesses present for the form to be legal.
D. Tell the daughter that if there are other children, they must be present for the form to be valid.
E. Tell the daughter that she must be the health care proxy for the form to be legally binding.

Answer: A. When an elderly patient has delirium or is confused because of another medical condition, he or she may lack the capacity to enter into a legal agreement or sign a legal document. The patient described is clearly too confused to understand all of the ramifications of signing his home over to another person. Confusion resulting from delirium or dementia is a risk factor for elder financial abuse.

186.4. An 85-year-old female with dementia, who lives in a skilled nursing facility, presents with bruises on her bilateral inner thighs. The facility staff states that she sustained these while being lifted from her bed to a chair. Who should you notify?
A. Adult protective services (APS)
B. Law enforcement
C. Sexual assault response team
D. The long-term care ombudsman
E. All of the above

Answer: E. The physical findings are concerning for sexual abuse. Therefore law enforcement and APS should be called, as well as the sexual assault response team to collect forensic evidence. Because the patient lives in a facility, the long-term care ombudsman should also be called to investigate the possible abuse.
PRINCIPLES

As greater numbers of immunocompromised persons present to the emergency department (ED), it is essential that emergency clinicians possess the knowledge and skills to recognize and treat infectious complications of cancer, organ transplantation, diabetes, renal failure, cirrhosis, asplenism, human immunodeficiency virus (HIV) infection, and other immunosuppressive conditions. These include infectious complications of immunosuppressive and immunomodulating medications used for a wide variety of disorders.

Compared with individuals with an intact immune system, infections in immunocompromised patients are more common, progressive, and severe, and they are caused by a wider variety of microorganisms. Immunocompromised persons who present with acute infections may appear deceptively benign initially. They may present with symptoms and signs that mimic noninfectious complications, only to deteriorate rapidly if they are not evaluated and treated urgently. Many interrelated factors cause patients to become immunocompromised and predispose them to the development of infections with potentially pathogenic microorganisms. These include disruption of the body’s protective surfaces, such as skin and mucosal barriers (oral and respiratory mucosa and intestinal and genitourinary surfaces); disorders that directly impair the function of the body’s immune system (eg, lymphoma, asplenism, and myeloma); drugs and irradiation that suppress or alter immune function; alterations in body substances governed by peristalsis and mucosal shedding help maintain normal numbers of microbes that often overwhelm natural clearance. Gastric acid and pancreatic enzymes have antibacterial properties that prevent overgrowth in the upper gastrointestinal tract. This mechanism is impaired with smoking and pulmonary disease. Mechanical ventilation or tracheostomy introduces large numbers of microbes that often overwhelm normal clearance. Gastric acid and pancreatic enzymes have antibacterial properties that prevent overgrowth in the upper gastrointestinal tract. Normal peristalsis and mucosal shedding help maintain normal gut flora. Alterations in these factors increase susceptibility to infection. Broad-spectrum antibiotics alter normal flora, permitting overgrowth of pathogens, such as Candida species, multiantibiotic-resistant bacteria, and Clostridium difficile.

Immunity and Immune Deficiency

The body’s defense mechanisms consist of surface barriers, such as skin, enzymes, and mucus, as well as innate (natural) and acquired (adaptive) responses. Innate responses occur to the same extent regardless of how often the body encounters the infectious agent, whereas acquired responses improve on repeated exposure. Innate immunity is activated immediately on exposure to an infecting agent, rapidly controlling replication and allowing the requisite 3 to 5 days for the adaptive component to clone sufficient T and B cells to respond more specifically.

Non–Microbe-Specific Immunity

Physical Barriers. Physical barriers, the first line of defense against microorganisms, consist of intact skin, gastrointestinal and respiratory mucosa, cilia, biofilm, gastric acid, antibacterial substances in pancreatic and biliary secretions, antimicrobial peptides and proteins on skin and mucous membranes, and resident microflora. In the respiratory tract, mucociliary transport and the cough reflex remove particulate matter and microbes. This mechanism is impaired with smoking and pulmonary disease. Mechanical ventilation or tracheostomy introduces large numbers of microbes that often overwhelm normal clearance. Gastric acid and pancreatic enzymes have antibacterial properties that prevent overgrowth in the upper gastrointestinal tract. Normal peristalsis and mucosal shedding help maintain normal gut flora. Alterations in these factors increase susceptibility to infection. Broad-spectrum antibiotics alter normal flora, permitting overgrowth of pathogens, such as Candida species, multiantibiotic-resistant bacteria, and Clostridium difficile.

Initial Inflammatory Response and Innate Immunity. The initial inflammatory response to microbial invasion acts to promote phagocytosis and microbial killing and to activate the immune system. Sentry cells detect pathogens, immediately triggering inflammation. This innate immune response is not dependent on prior exposure to the pathogen. The initial inflammatory response factors, mainly produced in the liver, activate many cell types to synthesize and to release cytokines, chemokines, and “trigger molecules” that kill the invading organism. This response delivers humoral and cellular immune components to sites of inflammation and initiates antibody responses. Cytokines, platelet-activating factor, and hormone-like proteins, including interferons, are secreted from various immune cells and play important roles in mediation of this response. Cytokines cause migration and adhesion of polymorphonuclear leukocytes and monocytes to sites of bacterial invasion. These cells release granules of substances that mediate vasodilation and increased vascular permeability, leading to edema, warmth, and redness, but also allow both phagocytic cells and humoral components to be concentrated at the site of infection.

A family of distinct transmembrane proteins, called Toll-like receptors, are found on many cell types, including macrophages, neutrophils, dendritic cells, mucosal epithelial cells, and endothelial cells. They recognize molecular patterns associated with microorganisms even in the absence of prior exposure, alert the host to the presence of the infectious agent and rapidly initiate a cascade of processes to activate innate immune responses, and help bridge innate and adaptive immune responses.

Reticuloendothelial System. The reticuloendothelial system, composed of tissue macrophages and their blood-borne counterparts, monocytes, removes particulate matter, including microbes, from the lymph and blood. The tissue component is concentrated in the lymph nodes, spleen, liver, marrow, and lung and has particular affinity for encapsulated bacteria, such as...
pneumococci, meningococci, and *Haemophilus influenzae*. The vital importance of this non–microbe-specific system is demonstrated by the overwhelming sepsis from encapsulated organisms in patients with asplenia.

**Adaptive (Microbe-Specific) Immunity**

**Humoral Immunity**

**Antibodies.** Antibodies are produced by B lymphocytes, and each B cell produces a single microbe-specific antibody type. Stimulation by an antigen (or microbe) causes proliferation of this particular B cell so that large quantities of a specific circulating antibody can be produced. Furthermore, B cells are active in presenting antigens to T lymphocytes, which promotes cell-mediated immunity (CMI).

**Immunoglobulins.** Immunoglobulin 

**Antibody.** IgM is detectable earlier in serum than IgG and serves as a marker for a patient’s early response to acute infection.

**Secrecory immunoglobulin A (IgA) is the predominant immuno**

**Humoral Immunity**

**Complement.** The complement cascade, a complex interaction of 30 proteins, is another crucial component of humoral response. Complement is important in producing inflammation and leukocytosis and in recruiting leukocytes to sites of infection by production of chemoattractants. Complement also neutralizes viruses, enhances opsonization of bacteria, and produces bacterial cell wall and membrane lysis.

**Both IgG and IgM, when they are in contact with an antigen, activate the classical pathway, whereas molecules with repeating chemical structures (eg, bacterial cell walls and capsules) activate the cascade through the alternative pathway. Components of C3, the merging point of the classical and alternative paths, provide opsonization and modulate the response of lymphocytes (CMI).**

**Opsonization is important in defense against infection with *S. pneumoniae*, Streptococcus pyogenes, *H. influenzae*, and *Staphylococcus aureus*. The terminal leg of the cascade, C5 through C9, forms the membrane attack complex, which inserts into cell walls and membranes and leads to cell death.**

**Individuals with inherited complement deficiencies are predisposed to frequent and recurrent infections with *S. pneumoniae*, *H. influenzae*, and especially *Neisseria meningitidis* and *Neisseria gonorrhoeae*. The risk of meningococcal infection is increased several thousandfold and most often develops in people deficient in C3 and in late complement components (C5 to C8). Paradoxically, the disease is usually milder with complement deficiency, and mortality is likewise reduced fivefold to tenfold. This suggests that the host response may be, in part, responsible for the severity of disease in normal individuals and is attenuated in complement deficiency. People with meningococcemia should be tested for inherited complement deficiencies, because they may benefit from immunization. Acquired deficiencies of complement function may develop in people with rheumatologic diseases, especially systemic lupus erythematosus (SLE). Approximately 40% of patients with SLE have an inhibitor of C5a-derived chemotaxis in their serum that results in enhanced susceptibility to infection.

**Cell-Mediated Immunity.** CMI includes immune responses that are mediated by T lymphocytes, natural killer (NK) cells, and mononuclear phagocytes. CMI is vitally important in the control of infections caused by microbes that survive and replicate intracellularly, including most viruses and some bacterial (obligate and facultative intracellular types), fungal, and protozoan pathogens.

**Only 5% of lymphocytes are in circulating blood. Most mature and are active in the marrow, thymus, spleen, and lymph nodes. The last two sites expose T cells to circulating antigens from invading microbes.** Specialized antigen-presenting cells in the lymphoid system sequester antigen and antigen-antibody complexes and present them to T cells. This process involves internalization and processing of the antigen, followed by formation of peptides that bind to a cell surface molecule called the major histocompatibility complex (MHC). Only with this specific presentation can a T lymphocyte become activated against a particular antigen.

**Two major types of T lymphocytes are CD4 (helper cell) and CD8 (suppressor cell), corresponding to type II and type I of MHC, respectively. CD4 lymphocytes provide help for other cells in the immune system, including enhanced B-cell antibody production and production of cytokines. CD8 lymphocytes are generally cytotoxic and mediate the eradication of virally infected target cells and certain tumors. A decline in the number of CD4 cells, with predominance of CD8 cells, is responsible for the increased susceptibility to infection in patients with acquired immunodeficiency syndrome (AIDS).** Despite the cytotoxicity of CD8 cells, immunity is reduced without adequate numbers of CD4 cells.

**Patients with defects in CMI are at increased risk for disseminated infection with intracellular bacteria, such as *Mycobacterium tuberculosis*, *Listeria monocytogenes*, and *Salmonella* species. The DNA viral infections, such as cytomegalovirus, herpes simplex, and varicella-zoster, also affect these patients more severely, as do fungal infections with *Candida*, *Cryptococcus*, *Mucor*, *Aspergillus*, and *Pneumocystis*. Finally, some protozoa are pathogenic in patients without intact CMI, such as *Toxoplasma gondii*. Some infections are seen only below a certain CD4 cell count. *Pneumocystis pneumonia*, for example, is seen almost exclusively in patients with counts below 200 cells/mL (2 × 10^5 cells/L), whereas almost all patients with toxoplasmosis or cryptococcal meningitis have counts below 100 cells/mL (1 × 10^6 cells/L).**

**NK cells, closely related to lymphocytes but neither B nor T cells, are important in the innate immune response and are found in high concentrations in blood and spleen.** NK cells recognize infected cells and respond by directly killing these cells, and they secrete cytokines that activate macrophages to destroy phagocytosed microbes. NK cells are important in defense against intracellular microbes, particularly viruses and intracellular bacteria such as *L. monocytogenes*.

**Granulocytic Phagocytes.** Granulocytic phagocytes are the cellular effectors of microbe killing, engulfing them and enzymatically lysing their cell membranes or walls. Two major types are polymorphonuclear leukocytes (neutrophils) and macrophages (the tissue version of circulating monocytes). Macrophages have surface receptors that recognize nonvertebrate carbohydrates, such as mannose, which form the cell wall of some microorganisms. Hence, they can identify and attack “invaders” rather than “self.”
Two other types of granulocytes, eosinophils and basophils, are less involved in the ingestion of organisms. Eosinophils mediate the destruction of certain parasitic helmiths through release of toxic proteins. Normally only 3% of total granulocytes, this cell type can reach 20% during times of high parasite load. Basophils (rare in circulation) and their tissue counterparts, mast cells, have high affinity for IgE. On exposure to antigens, they release granules with histamine, prostaglandins, and leukotrienes, which affect the allergic-inflammatory response with increased vascular permeability, bronchospasm, and vasodilation.

Neutrophils constitute 90% of circulating granulocytes and spend only 6 to 8 hours of their average 4-day life in circulation (the remainder in tissues). Effective antibacterial activity depends on the ability of neutrophils to travel to sites of infection, a process known as chemotaxis. The locomotion of neutrophils along vascular endothelium is facilitated by adherence to cell surface proteins whose production is enhanced in the initial inflammatory response.

Half of all neutrophils that leave the bone marrow circulate in the plasma. The other half become marginalized, adhering to endothelium, primarily in the lungs, liver, and spleen. During periods of stress or with endogenous or exogenous catecholamines or corticosteroids, these neutrophils demarginate and enter the circulation. As long as the patient is not neutropenic, demargination causes an increased peripheral neutrophil count composed of mature cells, whereas with bacterial infection, an increased proportion of immature (band) forms and is more typically seen.

Neutrophils (and macrophages in tissue) bind to and ingest bacteria through phagocytosis. This process is enhanced by proteins called opsonins that bind to bacterial surfaces. C-reactive protein, one of the initial inflammatory response proteins, fulfills this function for certain bacteria, including *S. pneumoniae*. IgG and complement protein C3b also opsonize bacteria, again illustrating the interdependence of the immune system. Actual killing takes place within granulocytes when cytoplasmic granules enzymatically produce potent oxidants. Granulocytes further control bacterial proliferation at the site of infection by elaborating lactoferrin, which locally binds free iron necessary for bacterial replication.

In addition to phagocytosis, macrophages (located in the spleen, alveoli, liver, and lymph nodes) modulate the immune response by presenting antigens to lymphocytes and releasing cytokines and complement components. Activation of macrophages to ingest bacteria depends on interaction with interferon-γ, a cytokine manufactured by T cells. Thus the once clear demarcation between cellular and humoral immunity is breaking down as more is understood about the interdependence of the immune system.

**SPECIFIC DISORDERS**

**Solid Organ Transplants**

For specific issues regarding medication induced immunocompromised states in solid organ transplant patients, refer to Chapter 188.

**Cancer**

Patients with cancer frequently have multiple immune defects, such as neutropenia and impaired function of T and B cells, induced by cancer chemotherapy or by the disease process itself, which predisposes them to infection. Other factors leading to infection are defects in physical barriers (skin and mucous membranes), including cytotoxic effects of chemotherapy on cells lining the gastrointestinal tract. In addition, splenic dysfunction or splenectomy, use of long-term intravascular catheters, frequent use of complex invasive diagnostic and therapeutic procedures, toxic effects of radiation therapy, and frequent colonization with antimicrobial-resistant pathogens are predisposing factors to immune system compromise. Cancer treatments (eg, allogeneic bone marrow and autologous stem cell transplantation, platelet transfusion, granulocyte colony-stimulating factor) increase survival during episodes of profound immunosuppression, allowing patients to receive more intense cytotoxic cancer chemotherapy regimens. These therapies enhance long survival of patients with neoplastic diseases that were formerly rapidly fatal. Despite many advances in supportive care, infections continue to result in serious morbidity and mortality. Furthermore, increasing resistance to antimicrobials is occurring among common pathogens along with the emergence of new opportunistic pathogens. Infection is much more common in patients with acute leukemia and lymphomas (75% of patients) and multiple myeloma (50% of patients) than in those with solid tumors. Immune system defects in the immunocompromised patient and the most common pathogens associated with each defect are listed in Box 187.1.

**Neutropenia**

**Background**

*Neutropenia* is defined as a neutrophil count of less than 500 cells/mL (5 × 10⁵ cells/L), including band forms, or less than 1000 cells/mL (1 × 10⁶ cells/L) and expected to fall to less than 500 cells/mL. It usually results from cytotoxic chemotherapy or radiation therapy or the disease process, especially in hematologic malignant neoplasms. In addition, cancer chemotherapeutic agents and radiation therapy can cause functional defects in granulocytes. The risk of febrile neutropenia and mortality is higher in the first one or two cycles of multicycle cytotoxic chemotherapy regimens. In a large nationwide study in the United States of febrile neutropenia among patients with metastatic solid tumors, febrile neutropenia occurred in 13% to 20% of patients during their chemotherapy course with a mortality of 4% to 10%, depending upon cancer type, and most often occurred in the first chemotherapy cycle.

The incidence and severity of infection in cancer patients with neutropenia are inversely proportional to the absolute neutrophil count and directly proportional to the duration of neutropenia. Although the incidence begins to rise as the neutrophil count falls below 500 cells/mL (5 × 10⁵ cells/L), most severe infections and almost all bacteremias occur when the neutrophil count is less than 100 cells/mL. Fever in the neutropenic patient is defined as a single temperature of 38.3°C (101°F) or higher or a temperature of 38.0°C (100.4°F) or higher during 1 or 2 hours.

In neutropenic patients, the temperature should be measured orally or tympanically, not rectally. Although fever can be suppressed or lessened by immunosuppressive agents such as corticosteroids and nonsteroidal antiinflammatory drugs, most cancer patients with infection manifest fever despite the use of these agents. Also, although uncommon, immunocompromised patients can have serious local or systemic infections without fever. These infections may be manifested by unexplained tachypnea or tachycardia, mental status changes, metabolic acidosis, increased volume requirements, rapid changes in serum glucose or sodium concentration, or acute abdominal pain. Because the onset of life-threatening infections can be rapid in cancer patients with severe neutropenia or a history of splenectomy, urgent evaluation and initiation of antimicrobial therapy are essential. A prospective multicenter observational study of febrile neutropenic cancer patients in EDs in France found that high-risk critically ill patients were poorly recognized and undertreated, low-risk patients were overtreated, and compliance with established guidelines was low.
The most common sites of infection in neutropenic patients are the lung (25%); mouth and pharynx (25%); gastrointestinal tract (15%); skin, soft tissue, and intravascular catheters (15%); perineum and anorectal area (10%); urinary tract (5%); and nose and sinuses (5%). Pneumonia and anorectal infection are more likely to be associated with bacteremia. Bacteremia may occur without an obvious source despite intensive investigation. The most important bacteria producing infection in neutropenic patients are three gram-negative bacilli—Escherichia coli, Klebsiella pneumoniae, and Pseudomonas aeruginosa—and four gram-positive cocci—Staphylococcus epidermidis, viridans group streptococci, Enterococcus species, and S. aureus. An increase in formerly uncommon gram-negative infections caused by Enterobacter, Citrobacter, and Serratia species has occurred, and infections caused by gram-negative organisms resistant to cephalosporins, extended-spectrum penicillins, and carbapenems are occurring more frequently. Anaerobes are uncommon but may be important in certain mixed infections (eg, mouth, abdominal, and perianal).

Infections caused by gram-positive organisms (eg, coagulase-negative staphylococci, S. aureus, viridans streptococci, and Enterococcus species) are now the leading cause of bacterial infection (50% to 70% at some centers) in febrile neutropenic cancer patients in the United States, Canada, and western Europe. Gram-negative organisms still predominate in developing countries. With the exception of viridans streptococci, most of these gram-positive organisms do not produce immediately life-threatening infections compared with the rapid lethality of many gram-negative infections. Life-threatening bloodstream infections caused by viridans streptococci (especially Streptococcus mitis), which can result in rapid development of a shock syndrome and/or acute respiratory distress syndrome, are now common in many cancer centers and often respond poorly to penicillins and cephalosporins. Risk factors for serious viridans streptococcal infections include aggressive cytoreduction therapy for acute leukemia or allogeneic bone marrow transplantation (especially after high-dose cytosine arabinoside treatment), profound neutropenia, and severe oral mucositis. Other factors include prophylactic use of
trimethoprim-sulfamethoxazole or fluoroquinolones, use of antacids or H₂ receptor antagonists, and childhood.⁷

Aspergillus and Candida species are the most common fungi producing infection in cancer patients with fever and neutropenia.⁸ Infection is most likely to develop in neutropenic patients treated with broad-spectrum antimicrobials and in those whose fever persists for more than 7 days. Aspergillus species usually produce necrotizing infections in the lung or sinuses. Pulmonary aspergillosis is often manifested with pleuritic pain, hemoptysis, and localized wheezing. The chest radiograph demonstrates pleural effusion or focal infiltrates. Computed tomography (CT) is more sensitive in detection of pulmonary infiltrates compatible with aspergillosis, and it may demonstrate a distinct halo of low attenuation surrounding a pulmonary infiltrate. This pattern is highly suggestive of invasive aspergillosis, although mucormycosis and other disorders may mimic the halo. Invasive aspergillosis originating in the paranasal sinuses may extend to the surrounding bone and brain. Often, an initial red-purple lesion on the nasal turbinates or palate turns pale and then black as vascular invasion produces infarction of the mucosa and bone. The black eschar on the nose or palate is easily misdiagnosed as dried blood. Patients presenting with head or facial pain or swelling, or proptosis, should be rapidly evaluated for invasive aspergillosis because these patients are unable to mount a full inflammatory response to a site of infection. Use of a single antimicrobial agent is preferred in most patients, especially when the neutrophil count is less than 100 cells/mL (1 × 10⁵ cells/L). When pneumonia develops, purulent sputum may be absent, and the initial chest radiograph may not show an infiltrate but will be more likely found by CT scan. Pyuria may be absent in patients with urinary tract infection. Areas of cellulitis may have minimal induration and redness and little or no purulent drainage. Tenderness may be the only finding in perineal and anal infections. The neutropenic patient with a documented infectious cause of fever may be difficult to distinguish from the patient with fever not caused by infection. The neutropenic patient with a localized infection may have shaking chills and a toxic appearance, without localized findings, and may not have demonstrated bacteremia. Only 20% of febrile neutropenic patients have a clinical focus of infection identified at presentation, and only 30% of patients have positive blood cultures.

Mucositis involving the mouth and other mucous membranes is a painful and debilitating condition that commonly occurs in cancer patients receiving intense chemotherapy. It is a frequent prelude to viridans streptococcal bacteremia, which can produce sudden onset of acute respiratory distress syndrome, a toxic shock–like syndrome, rash, and pneumonia.

Evaluation and Management

Box 187.2 describes a step-by-step approach to the evaluation and management of the adult patient with febrile neutropenia.

### Antibiotic Therapy

Broad-spectrum antimicrobial therapy should be initiated promptly in the febrile neutropenic patient.⁹ Moreover, even afebrile neutropenic patients who have symptoms and signs (eg, abdominal pain and tenderness) compatible with an infection should be treated empirically (Table 187.2).

Use of a single antimicrobial agent is preferred in most patients, because there is no conclusive evidence of a benefit from multiple drugs.³⁴ Antimicrobial resistance varies widely; and in the absence of a written hospital-specific protocol, immediate consultation with an oncologist or an infectious diseases specialist may be of great assistance.

Monotherapy with intravenous cefepime (favored at most cancer centers), meropenem, imipenem, or piperacillin-tazobactam is preferred, with an aminoglycoside (gentamicin, tobramycin, or amikacin) added for the more seriously ill patient.⁴ Monotherapy, without an aminoglycoside, may be advantageous in the patient with mild to moderate renal dysfunction or for patients receiving nephrotoxic agents, such as cisplatin, cyclosporine, or amphotericin B. Empirical use of ceftazidime is not recommended.⁴ None of these antimicrobial agents are active against vancomycin-resistant Enterococcus species or methicillin-resistant staphylococci.

For patients who are allergic to β-lactam antibiotics (eg, penicillins, cephalosporins, meropenem, and imipenem), coverage of gram-negative bacilli, including P. aeruginosa, can be provided by aztreonam. Because aztreonam is not active against gram-positive organisms, it should be combined with vancomycin. If anaerobes are suspected (ie, oral, abdominal, or perianal infection) in the β-lactam–allergic patient or in the patient receiving cephalosporin monotherapy, an antianaerobic drug (such as, clindamycin or metronidazole) should be administered. Empirical treatment with intravenous fluoroquinolones is not recommended in the febrile neutropenic cancer patient because of frequent prophylactic use of these agents in the cancer patient, risk for rapid emergence of
Evaluation and Management of the Adult Cancer Patient With Febrile Neutropenia in the Emergency Department

- Fever or history of fever is present, or patient has symptoms/signs of acute infection without fever.
- Complete blood count shows neutropenia (neutrophil count <500 cells/mL, including band forms, or <1000 cells/mL and expected to fall to <500 cells/mL).
- Careful monitoring of vital signs, including pulse oximetry; intravenous fluids as required.
- Obtain blood for measurement of electrolytes, renal and hepatic function, and serum lactic acid.
- Obtain blood cultures from each lumen of any existing central venous catheters and from at least one peripheral site, or two blood cultures from separate venipunctures of peripheral veins if no central venous catheter is present.
- Careful history and examination to search for subtle symptoms or signs of infection, with particular attention to the mouth, nose and sinuses, lower esophagus, lung, and skin, including nails, perineum including anus, bone marrow aspiration sites, and vascular catheter sites.
- Obtain chest radiograph if symptoms or signs of respiratory disease are present.
- Obtain urinalysis and urine culture if symptoms or signs of urinary tract infection are present.
- Obtain stool for culture for routine pathogens and PCR testing for *Clostridium difficile* if acute diarrhea or if acute abdominal pain without diarrhea is present.
- Obtain specimens for culture from any site of infection, including inflamed or draining catheter exit sites.
- If severe mucositis, obtain herpes simplex culture (or PCR testing) if not receiving antiviral prophylaxis, and obtain smear (Gram stain) for *Candida* pseudohyphae.
- Lumbar puncture is not recommended as a routine procedure unless subtle symptoms or signs of meningitis are present.
- Consider ultrasonography over a subcutaneous tunneled catheter track and its vein of insertion, which may reveal the presence of an abscess or infected thrombus.
- Assess for risk of complications: High risk includes patients with hypotension, pneumonia, new onset abdominal pain, neurologic changes, or other acute organ dysfunction (especially renal or hepatic dysfunction, or active COPD).
- Calculate the MASCC score if outpatient therapy is being considered in a stable patient.
- Initiate empirical intravenous antimicrobial monotherapy with an anti-pseudomonal beta-lactam agent (cefepime, meropenem, imipenem-cilastatin, or piperacillin-tazobactam) as soon as possible after cultures are obtained.
- Other antimicrobials (such as, an aminoglycoside and/or vancomycin) may be added for hypotension or pneumonia (ie, azithromycin) or if antimicrobial resistance is suspected.
- For suspected polymicrobial anaerobic infections (such as, intraabdominal or perianal source), add an anaerobic drug (metronidazole or clindamycin) if cefepime is used as the beta-lactam agent.
- For patients with a minor penicillin allergy, empirical treatment with cefepime, meropenem or imipenem-cilastatin can usually be given safely.
- For patients with history of severe penicillin allergy, consult an infectious diseases specialist, or initiate empirical therapy with aztreonam and vancomycin, and add clindamycin or metronidazole if anaerobic infection is considered. Avoid empirical use of a fluoroquinolone as coverage for gram-negative bacilli in penicillin-allergic patients.
- Empirical use of vancomycin is not routinely indicated for all febrile neutropenic patients, but should be considered if there is suspicion for serious catheter-related infection; known colonization with MRSA or penicillin-resistant pneumococci; known isolation of a gram-positive organism before final identification and susceptibility is known; presence of shock; severe mucositis; prior fluoroquinolone prophylaxis; and institutions in which MRSA, vancomycin-susceptible enterococci, and *Streptococcus mitis* (viridans streptococcus group) are frequent pathogens.
- Empirical antifungal therapy is only rarely indicated in the ED and should not be initiated by the emergency physician without consultation with an infectious diseases specialist.
- Urgent CT scanning may be indicated:
  - If the chest radiograph is normal or inconclusive in a patient with acute respiratory symptoms/signs, consider obtaining a high resolution CT scan of the chest without contrast enhancement.
  - If facial pain or swelling is present, consider obtaining a CT scan of the sinuses without contrast enhancement.
  - In patients with abdominal pain and tenderness, obtain a CT scan of the abdomen and pelvis with intravenous contrast.
- Administration of empirical antimicrobial therapy should not be delayed while waiting for CT scanning or other diagnostic testing (other than cultures) to be performed.
- Contact the patient's oncologist early in the evaluation of these patients.
- Do not initiate outpatient therapy in low-risk patients without contacting the patient's oncologist and/or an infectious diseases specialist.
- Patients being considered for early discharge and outpatient management should have a MASCC score ≥21 and have no other high risk features; and they should be observed for at least 4 hours after the initial antibiotic dose to monitor for stability. Low-risk patients may be monitored in an ED observation unit where they can be evaluated by an oncologist and/or infectious diseases specialist to determine whether early discharge to home is feasible. Avoiding an inpatient admission is advantageous for the stable low-risk patient because hospitalization exposes the patients to potential iatrogenic complications and antimicrobial-resistant nosocomial pathogens, and outpatient admission allows an improved quality of life.

resistance in gram-negative bacilli, and predisposition to *C. difficile* infection.4

When a focus of infection is identified, empirical therapy should cover the most likely pathogens causing infections at the site. Patients with pneumonia may need coverage for *Legionella* (azithromycin or a fluoroquinolone), *Pneumocystis* (trimethoprim-sulfamethoxazole), or fungi (amphotericin B) in addition to standard antibacterial coverage. Agents effective against anaerobes (clindamycin, metronidazole, meropenem, imipenem, or piperacillin-tazobactam) should be considered for patients with perianal or oral infection and those with abdominal pain, who may have appendicitis, diverticulitis, or typhlitis (neutropenic enterocolitis). Acyclovir should be considered for patients with ulcerative or vesicular lesions who may have herpes simplex or varicella-zoster virus infections. In patients with severe mucositis and febrile neutropenia, meropenem, imipenem, or piperacillin-tazobactam, often combined with vancomycin, is preferred for empirical treatment because of superior efficacy against viridans streptococci.4

“Routine” empirical use of vancomycin for all febrile neutropenic cancer patients is not recommended because of concern about the development of vancomycin-resistant organisms.4,9
Randomized clinical trials show no survival advantage when vancomycin is used as the initial therapy for neutropenic patients, even those with indwelling catheters. Because most infections with gram-positive bacteria are indolent, vancomycin therapy can be safely delayed for 24 to 48 hours in most patients until a vancomycin-requiring gram-positive infection is identified.

Indications for initial empirical vancomycin therapy include serious catheter-related infections, known colonization with penicillin-resistant pneumococci or methicillin-resistant *Staphylococcus aureus* (MRSA), and positive blood culture for gram-positive organisms before final identification and susceptibility testing. Other indications include shock; severe mucositis; prior fluoroquinolone prophylaxis; and institutions in which MRSA, vancomycin-susceptible enterococci, and *S. mitis* are frequent pathogens.4 Patients previously colonized or infected with MRSA, vancomycin-resistant enterococci, extended-spectrum β-lactamase–producing gram-negative bacteria, and carbapenemase-producing organisms may require modifications to initial empirical therapy.4

Amphotericin B (and its lipid formulations) is the drug of choice for treatment of invasive fungal infections in patients with neutropenia.6,7,8,9,10 Up to one-third of febrile neutropenic patients not responding to 1 week of antibiotics have systemic fungal infections, usually *Candida* or *Aspergillus*. Antifungal agents (such as, caspofungin, voriconazole, or posaconazole) may be indicated in selected cases. Empirical use of fluconazole is not recommended because of lack of activity against *Aspergillus* and some *Candida* species.

**Cell Stimulation Therapy.** For prevention of chemotherapy-related neutropenia, some centers routinely use human recombinant hematopoietic or colony-stimulating growth factors (granulocyte colony-stimulating factor: filgrastim, pegfilgrastim; granulocyte-macrophage colony-stimulating factor: sargramostim) to stimulate the proliferation and maturation of bone marrow progenitor cells and to increase the number and function of these committed cell populations. They are safe and well tolerated but very expensive. Treatment with these agents after chemotherapy shortens the duration of neutropenia, may reduce the hospital stay and the duration of fever, and may reduce mortality in those at highest risk (elderly, comorbid conditions, multiorgan failure, recurrent febrile neutropenia), but current evidence does not support their use for all patients.4,11

**Risk Assessment and Disposition**

Febrile neutropenic cancer patients can be classified into high-risk and low-risk groups. Factors associated with high-risk include the following: status as inpatient when fever and neutropenia develop; presence of comorbid medical conditions; uncontrolled cancer; acute leukemia; hemodynamic instability; evidence of organ failure; presence of pneumonia, severe soft tissue infection, infection of a central line, abdominal pain, or neurologic or mental status abnormalities; and neutropenia expected to last more than 10 days. These patients should be treated in the hospital with intravenous antibiotics.

Outpatient empirical antibiotic therapy has been shown to be safe and efficacious in carefully selected febrile neutropenic adults who are not at high risk for medical complications.4,12–14 The Multinational Association for Supportive Care in Cancer (MASCC) risk index score (available at www.mascc.org/mascc-fn-risk-index-score) is an easy to use, validated clinical prediction rule for classification of low risk adults (Table 187.3, Box 187.3) but should not be used as the sole factor to decide on low-risk status or outpatient management.15 Three clinical practice guidelines, those of the Infectious Diseases Society of America, the American Society of Clinical Oncology, and the National Comprehensive Cancer Network, as well as the Cochrane Database of Systematic Reviews, support outpatient or short-stay oral antibiotic therapy in carefully selected low-risk patients with neutropenic fever.4,12–14 The only oral antibiotic regimen that is recommended is ciprofloxacin or levofloxacin plus amoxicillin-clavulanate (or plus clindamycin in penicillin-allergic patients).6,12

**Children With Cancer and Febrile Neutropenia**

Box 187.4 lists unique considerations in the evaluation and management of children with cancer and febrile neutropenia.16,17

**Non-Neutropenic Conditions in the Cancer Patient**

The Solid Organ Cancer Patient Without Neutropenia

Most solid organ cancer patients who have fever and infection are not neutropenic. Infections in these patients may occur after surgical procedures and can include wound infection, deep abscess, or perforated viscus. Infections may be associated with central venous or urinary catheters, stents, and prosthetic devices. In addition, solid tumor patients with large tumor lesions may have obstructive infections (of bronchus, bile duct, or ureter). The spectrum of microorganisms includes a wide variety of community-acquired organisms (bacterial, fungal, and viral), as well as nosocomial multiantibiotic-resistant pathogens.

Prompt initiation of antimicrobial therapy in the febrile non-neutropenic solid cancer patient is not always indicated. Rapid

Neutropenia and Cancer

Management of Children With Febrile

BOX 187.3

Considerations for Outpatient Management of Cancer Patients With Febrile Neutropenia

Adult patients may be considered for outpatient therapy if:

• Patient should have a MASCC score ≥21.
• Patient is medically stable without acute or chronic organ dysfunction or comorbid conditions and does not have acute leukemia.
• No focus of infection identified: Patient does not have pneumonia, infection of a central line or a severe soft tissue infection, and does not have acute abdominal pain or an intra-abdominal infection.
• Patient has access to a telephone and transportation to return to hospital available 24 hours a day and has a caregiver at home.
• Patient has a history of compliance with follow-up and treatment protocols.
• Patient is not on fluoroquinolone prophylaxis and there is a low prevalence of fluoroquinolone-resistance in the community.
• Patient’s oncologist agrees to outpatient management.
• The emergency clinician should contact the patient’s oncologist and/or an infectious diseases specialist before considering outpatient therapy.

Patients being considered for outpatient therapy should be observed for at least 4 hours in the ED (or in an ED observation unit) after the initial antibiotic dose, which should be administered intravenously as soon as possible after initial cultures are obtained. The only recommended outpatient oral antimicrobial therapy for these patients is ciprofloxacin or levofloxacin plus amoxicillin/clavulanate (or plus clindamycin for those with penicillin allergy).

ED, Emergency department; MASCC, Multinational Association for Supportive Care in Cancer.

BOX 187.4

Unique Considerations for Evaluation and Management of Children With Febrile Neutropenia and Cancer

• Because intravenous catheter infections are a common source of fever in children, obtain blood cultures from all lumens of indwelling central venous catheters.
• Obtain a peripheral vein blood culture if possible (may not be possible in small children).
• Obtain urinalysis and urine culture, because urinary tract infections are frequent causes of fever in neutropenic children.
• Obtain chest radiograph only in children with symptoms or signs of respiratory disease.
• Initiate monotherapy with an anti-pseudomonal beta-lactam or carbapenem as empirical therapy (cefepime, meropenem, imipenem-cilastatin, or piperacillin-tazobactam) as soon as cultures have been obtained. Avoid empirical use of ceftazidime monotherapy.
• Some low risk children with febrile neutropenia who have access to close follow-up may not require hospital admission and may be discharged home after a period of observation, but this should only be attempted after consultation with the patient’s oncologist and/or an infectious diseases specialist.
• Transfer of the pediatric cancer patient with febrile neutropenia to a hospital experienced in the management of children with cancer is recommended.

Surgical intervention may be more important than the urgent initiation of empirical antibiotics. In febrile non-neutropenic cancer patients who are not ill-appearing and have no identified focus of infection, it may be appropriate to obtain culture specimens and to observe the patient. After consultation with an oncologist, some patients can be discharged home with close follow-up. Indications for urgent antibiotics include signs of sepsis, mental status changes, lactic acidosis, shock, abdominal pain, history of splenectomy, and identification of a focal site of infection.*

Impaired Cell-Mediated Immunity

The T-cell defects resulting from impaired CMI in cancer patients usually result from cancer chemotherapy or corticosteroid treatment. The cancer itself impairs CMI in patients with Hodgkin’s disease, non-Hodgkin’s lymphoma, and hairy cell leukemia.

Bacterial Infections. L. monocytogenes is one of the more common bacterial organisms infecting cancer patients with impaired CMI. Listeria infection is also seen in patients with organ transplants, diabetes, cirrhosis, AIDS, late pregnancy, and in those receiving high-dose corticosteroids or biologic therapies (infliximab and related drugs). No early characteristics distinguish Listeria infection from bacteremias caused by other organisms. Meningitis, which may be accompanied by cerebritis or brain abscess, is the most common focus of infection and may be manifested with personality changes or focal neurologic signs. Cerebrospinal fluid examination frequently does not reveal the organism on Gram’s stain, but protein is elevated and pleocytosis is present. Treatment should be with ampicillin and gentamicin. Trimethoprim-sulfamethoxazole is the alternative drug for patients with penicillin allergy. Vancomycin is not effective in treatment of Listeria infections even when in vitro susceptibility is shown. Cephalosporins, such as ceftriaxone and cefotaxime, are not active against Listeria.

Infections caused by Salmonella species are common in patients with impaired CMI and usually are manifested with fever with or without enteritis. Bacteremia can result in infection of bones, joints, central nervous system, and endovascular devices. Multidrug-resistant Salmonella species are increasing. Treatment usually includes a third-generation cephalosporin or a fluoroquinolone, because many isolates are resistant to ampicillin and trimethoprim-sulfamethoxazole.

Patients with solid tumors, lymphoma, and leukemia (especially hairy cell leukemia) are at increased risk for pneumonia from Legionella species, with the highest risk in cancer patients receiving high-dose corticosteroids. Non-pneumophila species of Legionella (eg, Legionella micdadei and Legionella bozemanii) are particularly common in these patients. Clinical and radiographic manifestations of Legionella infection in the immunocompromised patient often differ from those in the immunocompetent host. For example, pleuritic chest pain may be a prominent symptom in the immunocompromised patient and may mimic pulmonary embolism. These patients can have fever without any other symptoms of pneumonia despite the presence of radiographic pulmonary infiltrates. In addition, the chest radiograph may reveal an expanding pulmonary nodule or cavitation of a nodule or infiltrate rather than the usual lower lobe alveolar filling defects. Pyonatremia (serum sodium <130 mEq/L [mmol/L]) is particularly common. Although gastrointestinal and neurologic symptoms and elevated serum transaminase levels are common in patients with Legionella infections, these are not more common in patients with Legionella than in those with other causes of pneumonia. The treatment of choice for immunocompromised patients with suspected Legionella infection is a respiratory fluoroquinolone or azithromycin.

Nocardios is an uncommon but often severe bacterial infection caused by a weakly acid-fast gram-positive branching filamentous rod. It occurs in cancer patients, in those receiving high-dose corticosteroids, and in others with defective CMI. Subacute pneumonia with nodular infiltrates is the most common manifestation, usually without fever, but Nocardia may also produce cellulitis, subcutaneous abscesses, meningesis, and brain abscess. Diagnosis requires biopsy, tissue stains, and culture. Treatment is with sulfonamides often combined with other agents.

**Mycobacterial Infections.** Tuberculosis and other mycobacterial diseases may produce severe disease in those with defective CMI and be manifested as fever of undetermined origin, pneumonia, lymphadenopathy, or skin lesions. It is easily mistaken for signs caused by the patient’s underlying disease or treatment. Disseminated nontuberculous mycobacterial infections are more common in patients with hairy cell leukemia or chronic myelogenous leukemia.

**Fungal Infections.** Infections with *Cryptococcus neoformans* and *Coccidioides immitis* occur in patients with Hodgkin’s and non-Hodgkin’s lymphoma, chronic myelogenous leukemia, and chronic lymphocytic leukemia, especially those taking high-dose corticosteroids. Patients with HIV infection, solid organ transplants, diabetes, renal insufficiency, and cirrhosis are also at risk, as are patients receiving prolonged high-dose corticosteroids for connective tissue disease. Meningitis is the most common manifestation, often with the insidious onset of low-grade fever and subacute (and often intermittent) headache. Many other organ systems can become infected, including the lung, skin, bones, and joints. Diagnosis is made by measurement of cryptococcal antigen (not antibody) in serum and cerebrospinal fluid and by fungal cultures and tissue biopsy.

Impaired CMI may result in reactivation of *Histoplasma capsulatum* and *Coccidioides immitis* with resultant disseminated disease. Infections with *Candida* species are also common in cancer patients with defective CMI, but disseminated disease is less likely than in patients with neutropenia. Invasive aspergillosis may develop in cancer patients receiving high-dose corticosteroids but not as commonly as in those with organ transplants or prolonged neutropenia. *Pneumocystis jiroveci* (formerly *carinii*) pneumonia is most common in patients with AIDS, leukemia, and lymphoma and in patients with solid tumors taking high doses of corticosteroids.

**Parasitic Infections.** Reactivation of central nervous system infection with the protozoan *T. gondii* occurs most often in cancer patients with lymphoma and leukemia as well as in HIV infection. *Strongyloides stercoralis*, an intestinal nematode, is the only helminthic organism producing severe infection in patients with deficient CMI, almost exclusively in those receiving high-dose corticosteroids. Larvae of the parasite disseminate from intestine to lung and other organs, including central nervous system and skin, causing the *Strongyloides* hyperinfection syndrome, with very high mortality. Wheezing, cough, dyspnea, hemoptysis, and hemorrhagic rash are common. Chest radiographs may show focal or diffuse infiltrates. Dissemination is often accompanied by bacterial infection, usually caused by enteric gram-negative bacilli carried by the parasites from the intestinal tract. Diagnosis is made by examination of stool, sputum, tissue or fluid (obtained by bronchoscopy or endoscopy), or cerebrospinal fluid for larvae of the parasite. The treatment of choice is oral ivermectin.

**Viral Infections.** The most common viruses producing serious infections in cancer patients with defective CMI are varicella-zoster, herpes simplex, and cytomegalovirus. Visceral dissemination is common in primary varicella (chicken pox) in nonimmune immunocompromised children and adults, with development of pneumonia, encephalitis, hepatitis, and hemorrhagic lesions. When a nonimmune immunocompromised child or adult is exposed to varicella, varicella-zoster immune globulin (VarizIG in the United States) should be administered as soon as possible after exposure, up to 10 days postexposure, to ameliorate the disease. Herpes zoster infection is common in cancer patients, particularly those with Hodgkin’s and non-Hodgkin’s lymphoma and leukemia. Disease usually remains localized to the primary dermatome, but dissemination occurs in approximately 11% of patients. Dissemination is usually limited to the skin, but visceral involvement (lung and liver) occasionally occurs. Skin lesions in primary varicella or zoster often become hemorrhagic in these patients.

Reactivation of herpes simplex virus is common, resulting in severe mucocutaneous infection in oral or genital areas. Spread may occur to the esophagus, lungs, or other organs. Herpetic lesions in cancer patients tend to be larger and deeper than those in the immunocompetent patient. Acyclovir given intravenously is the treatment of choice for varicella-zoster and herpes simplex infections in immunocompromised patients, but some stable patients may be treated with oral valacyclovir.

Cytomegalovirus infection may occur in cancer patients treated with corticosteroids. Measles virus, although uncommon, may produce severe infection in those with defective CMI. Fever, rash, pneumonia, and encephalitis are common manifestations. Immune serum globulin may be given after exposure to ameliorate disease. Common community respiratory viruses, such as respiratory syncytial virus, influenza, and adenovirus, may produce severe or fatal pneumonia.

**Humoral Immune (B-Cell) Defects**

Hypogammaglobulinemia is common in patients with chronic lymphocytic leukemia and myeloma. Low immunoglobulin levels predispose to infections with encapsulated bacteria, such as *S. pneumoniae*, *H. influenzae*, and *N. meningitidis*. Pneumonia is the most common manifestation, but sepsis, otitis media, cellulitis, and urinary tract infection may occur. After receiving cytotoxic agents and corticosteroids for treatment, these patients become susceptible to infections associated with impaired CMI, as well as bacterial infections caused by *S. aureus* and gram-negative bacilli, often with high mortality. Regular infusions of intravenous immune globulin may decrease the incidence of infection but do not prolong survival. Patients should receive pneumococcal vaccine, but many do not respond.

**Disruption of Natural Barriers**

Disruption of natural anatomic barriers (eg, mucous membranes and skin) by ulcerating tumors, chemotherapy, radiation therapy, diagnostic and therapeutic procedures, and catheters can lead to infection by gram-positive and gram-negative organisms, including anaerobes. Oral mucositis, a debilitating and intensely painful condition associated with radiation therapy and high-dose chemotherapy, frequently results in serious local and systemic infections, including life-threatening sepsis with viridans streptococci. Cancers may cause partial or total obstruction of body lumens and cavities, as does swelling and scarring from radiation therapy. Bronchial obstruction by tumor can lead to pneumonia. Obstruction of the urinary tract may result in infection. Gastrointestinal tract obstruction can lead to perforation and peritonitis.

**Opportunistic Infections Mimicking Neoplasm**

Infectious agents can produce laboratory, radiologic, or physical findings that resemble those caused by the spread of tumor. For
example, mass lesions in the brain caused by *Nocardia* or *Toxoplasma* can be mistaken for cancer metastases. *Aspergillus*, *Mucor*, *Rhizopus*, and related fungi invade blood vessel walls and produce thrombosis, which may result in Budd-Chiari syndrome (hepatic vein obstruction), nephrotic syndrome, or oculomotor palsy that may be misattributed to the spread of tumor. Renal vein thrombosis can be caused by infection with gram-negative bacilli. *Candida* fungus balls may develop in one or both ureters, producing a picture of postrenal obstructive uropathy. *Histoplasma*, *Pneumocystis*, *Legionella*, *Aspergillus*, *Nocardia*, and other organisms can produce pulmonary nodules and be mistaken for pulmonary metastases.

**Pulmonary Infections in the Immunocompromised Patient**

In neutropenic cancer patients, pneumonia is commonly caused by gram-negative bacilli early in neutropenia and by fungal organisms such as *Aspergillus* after prolonged neutropenia. In those with impaired CMI, cytomegalovirus, *Pneumocystis*, *Legionella*, *Nocardia*, mycobacteria, and fungal organisms predominate. Pneumococcal pneumonia is most common in patients with impaired humoral immunity. Patients with primary lung cancer or with pulmonary metastases from other cancers may develop postobstructive pneumonia, lung abscess, and empyema related to *S. aureus*, gram-negative bacilli, and anaerobes. Conditions mimicking pneumonia in the immunocompromised host include pulmonary emboli and infarction, congestive heart failure, metastatic or primary carcinoma, lymphangitic spread of carcinoma, alveolar hemorrhage, leukoagglutinin reactions, and radiation- and drug-induced pneumonitis. An acute presentation of “pneumonia” suggests bacterial pneumonia, pulmonary emboli, congestive heart failure, or pulmonary hemorrhage. Subacute presentations may suggest a fungal, nocardial, mycobacterial, or viral etiology (Table 187.4).

**Diabetes**

Diabetic patients have increased susceptibility to infection because of defects in immune function, excess substrate for fungal and bacterial growth, vascular insufficiency related to microangiopathy and atherosclerosis, and sensory neuropathy that leads to wound neglect. Neutrophil and monocyte-macrophage functions are also impaired in diabetic patients, including adherence to bacteria, chemotaxis, neutrophil degranulation, phagocytosis, and intracellular killing. These defects are exacerbated by hyperglycemia and improved by tight glucose control. Hyperglycemia disrupts C-type lectin function, which is an essential component of the immune system’s response to microbial invasion. Although decreased lymphocyte proliferative responses to phytohemagglutinin and certain pathogens are described, cellular immunity appears normal or only minimally affected by diabetes. Humoral immunity is normal in diabetics.

Infections seen with increased frequency in diabetic patients include rhinocerebral zygomycosis (formerly mucormycosis) caused by *Rhizopus* and *Mucor* species; malignant (or necrotizing) otitis externa caused by *P. aeruginosa*; pneumonia caused by *S. aureus* and gram-negative bacilli; tuberculosis, emphysematous cholecystitis, and urinary tract infections including emphysematous cystitis and pelonephritis; polymicrobial necrotizing fasciitis involving the perineum (Fournier’s gangrene) and lower extremities; and psoas abscess, spinal epidural abscess, foot infections with osteomyelitis, and postoperative site infections. Diabetics who inject insulin are frequently colonized in the nares and skin with *S. aureus* that may predispose to skin infections with transient bacteremia, which can seed distant sites. Women diabetics with hyperglycemia are predisposed to vulvovaginal candidiasis. Diabetics are not more likely to have pneumococcal pneumonia but are more likely to become bacteremic and to have a higher mortality rate.

**Alcoholism and Cirrhosis**

Alcohol consumption predisposes to infection through direct suppression of the immune system, alterations in blood flow, depression of mental status, and delay in seeking medical care. With alcoholic cirrhosis, there is deficient hepatic clearance and killing of bacteria by reticuloendothelial cells, as well as splenic hypofunction. Complement deficiency occurs because the liver is the primary site of C3 synthesis. Neutrophils show impaired recruitment to infective sites and defective chemotaxis and phagocytosis. Cellular immune deficiency occurs and is exacerbated by malnutrition. Bacterial activity of IgM antibody against gram-negative pathogens such as *E. coli* and *H. influenzae* is decreased.

Acute ethanol intoxication is associated with granulocytopenia and diminished leukocyte mobilization that is reversible with abstinence. Ethanol intoxication interferes with most respiratory tract defense mechanisms, resulting in alterations of normal flora, impaired mechanical and cellular clearance because of a suppressed cough reflex, decreased ciliary motility, and resultant aspiration. These effects are often compounded by malnutrition, cigarette smoking, and chronic lung disease. Alcoholics exhibit an increased incidence of oropharyngeal colonization by gram-negative bacteria (35% to 59% of ambulatory alcoholic patients) compared with control subjects (14% to 18%). Alcoholics are also more likely to aspirate because of loss of reflex glottic closure associated with acute intoxication, withdrawal seizures, and encephalopathy.

Common infections in patients with cirrhosis include spontaneous bacterial sepsis caused by *E. coli, K. pneumoniae, Salmonella*, streptococci, *Vibrio vulnificus*, and *Aeromonas*; spontaneous bacterial peritonitis, usually caused by *E. coli, K. pneumoniae, S. pneumoniae*, or enterococci; pneumonia related to pneumococci, gram-negative bacilli (*E. coli, K. pneumoniae, and H. influenzae*), and anaerobes; tuberculosis; meningitis caused by *S. pneumoniae* and *L. monocytogenes*; and skin and soft tissue infections with *S. aureus*, streptococci, and gram-negative bacilli. Nasopharyngeal and cutaneous diphtheria also occurs. Cirrhotic patients who present to the ED after a recent prior hospitalization often have health care–associated infections including catheter-related and *C. difficile* infections, spontaneous bacteremia, urinary tract infections, and pneumonia, often with high mortality. 33

**Renal Failure**

Infections are a major cause of death in patients with chronic renal failure and are the second most common cause of mortality after coronary artery disease. These patients are often diabetic, which increases their risk for serious morbidity and mortality from infections. Disruption of cutaneous barriers at vascular access sites and peritoneal dialysis catheter sites and numerous immune system defects are responsible for the increased incidence of infection. Uremic pruritus with excoriation, epidermal and sweat gland atrophy, dryness, and vesicular eruptions also compromise the cutaneous barrier. Reduced renal clearance of unknown toxins, nutritional deficiencies, and administration of immunosuppressive medications lead to aberrant immune regulation early in the course of renal failure.

Chronic kidney failure leads to a state of generalized immune hyporesponsiveness. Neutrophils show reduced mobility, chemotaxis, adherence, phagocytosis, and intracellular bactericidal activity, and leukopenia is commonly present. CMI is severely impaired, with decreased activation and proliferation of T lymphocytes and reduced NK cell activity, which cannot be reversed by hemodialysis. Furthermore, humoral immunity is adversely affected, resulting in deficient production of certain IgG subclass antibodies. Poor response to vaccines is common but can be improved by reinforced vaccination schedules, increased vaccine dosage, and adjunct immunomodulators. Additional predisposing factors to infection in uremic patients include low serum albumin, iron overload, increased intracellular calcium, circulating low-molecular-weight uremic toxins, metabolic acidosis, circulating inhibitors to chemotactic factors, decreased production of endogenous pyrogens, and invasive vascular procedures for dialysis access.

Severe infections with antibiotic-resistant bacteria (health care–associated infections) are common, and empirical therapy for a suspected serious infection should include broad-spectrum antimicrobials active against MRSA and antibiotic-resistant gram-negative bacilli. Skin and soft tissue infections, especially those caused by *S. aureus*, are particularly severe in diabetics and in those with peripheral vascular disease or peripheral neuropathy. Vascular access site infections are usually caused by *S. aureus* but occasionally by gram-negative bacilli and enterococci. Patients using central venous catheters for dialysis have much higher rates of sepsis compared with fistulas or grafts. Infections of dialysis access sites, often due to *S. aureus*, are life threatening and frequently associated with hematogeneous seeding of infection to distant sites, including osteomyelitis (usually involving the ribs or thoracic vertebrae), endocarditis, meningitis, epidural abscess, and septic arthritis. Pneumonia may be severe, and there is an increased incidence of *Legionella pneumonia*. Pneumonia may be difficult to diagnose by chest radiograph in these patients due to changing pulmonary fluid dynamics. Because mortality is high, early antimicrobial treatment should be administered if acute pneumonia is being considered after appropriate cultures have been obtained, with consideration of antimicrobial coverage for health care–associated pathogens. Tuberculosis and fungal infections caused by *Candida* species, *Cryptococcus*, *Histoplasma*, and *Coccidioides* occur with increased frequency. Diagnosis of tuberculosis may be difficult because of nonspecific symptoms and increased incidence of extrapulmonary disease.33 In addition, *C. difficile* infection occurs more frequently and is more severe with high mortality.33 Infections of the urinary tract are more prevalent, with urinary bladder catheterization the most frequent predisposing factor. There is a poor correlation between the presence of pyuria and urinary tract infection in these patients. *Candida* infection of the urinary tract may develop in patients with chronic renal failure treated with broad-spectrum antibiotics.

Up to two-thirds of patients receiving chronic peritoneal dialysis have peritonitis in their first year, and one-third may be forced to discontinue dialysis because of recurrent infections. *S. aureus* and *S. epidermidis* predominate, followed by streptococci, gram-negative bacilli, and *Candida* species. Fortunately, peritoneal dialysis patients have much lower rates of sepsis than those on hemodialysis.

**Splenectomy, Hyposplenemia, and Functional Asplenia**

The spleen is the most important organ in the reticuloendothelial system and is the primary site for IgM synthesis, which is the first early immune response of the body. Opsonin production in the spleen facilitates phagocytosis of bacteria by intracellular macrophages. Patients without spleens also have decreased production of neutrophils, NK cells, and immunomodulating cytokines. The spleen is the principal site of clearance of *S. pneumoniae* from the blood. Splenectomy or functional asplenia predisposes to overwhelming pneumococcal infection and fulminant infection with other encapsulated organisms (*H. influenzae, N. meningitidis*, and *Capnocytophaga canimorsus* after dog bites) and gram-negative bacilli (*E. coli and P. aeruginosa*).34 Asplenic patients who become infected with *Babesia microti*, a malaria-like protozoan transmitted by tick bite in the United States, may develop severe and often fatal hemolysis. Human granulocytic anaplasmosis (formerly ehrlichiosis), another tick-borne infection, is severe and sometimes fatal in asplenic patients. In addition, the gram-negative coccobacillus *Bordetella holmesii* produces a non–life-threatening acute febrile illness with bacteremia in patients with asplenia. Pneumococcal sepsis represents 50% to 90% of cases. Most healthy adults who die after fulminating pneumococcal sepsis have had a splenectomy or have a congenitally small or abnormal spleen.

The incidence of overwhelming postsplenectomy sepsis in these patients is low; but when it occurs, the mortality rate is high—especially in children with hematological disorders.35 The risk is greater in children than in adults, with children younger than 2 years old at greatest risk. The risk is highest in the first few years after splenectomy but persists throughout life into old age. People undergoing splenectomy for a hematologic disorder or lymphoma are at much higher risk for overwhelming postsplenectomy infection than are those undergoing splenectomy for trauma. This is probably because of the occurrence of splenic implants (splenosis) or accessory spleens in traumatized patients. Patients with functional asplenia from sickle cell anemia or thalassemia major are at high risk for overwhelming bacterial infections as well.

Functional hyposplenism occurs in a variety of conditions besides sickle cell disease, including sickle cell–hemoglobin C disease, ulcerative colitis, celiac disease, sarcoidosis, amyloidosis, rheumatoid arthritis, and SLE. The presence of anatomic or functional hyposplenism may be recognized by the finding
of Howell-Jolly bodies in red blood cells on a peripheral blood smear.

When overwhelming postsplenectomy infection occurs, often no obvious source of infection is found. Prodromal symptoms (such as, fever, rigors, malaise, myalgias, headache, vomiting, and diarrhea) may be present for 1 or 2 days. Patients seen at this time may be misdiagnosed as having a viral illness, gastroenteritis, or food poisoning. Abrupt deterioration then occurs over hours, with rapid progression to septic shock with disseminated intra-vascular coagulation, purpura, and multiorgan dysfunction. The mortality rate is high (50% to 70%), with younger children having the highest mortality rate. In addition, meningitis without overwhelming infection or shock is a common presentation of pneumococcal infection in asplenic patients. When fever develops in a person at risk for this disorder, treatment with an antimicrobial agent effective against \textit{S. pneumoniae} should be initiated without delay. After blood culture is performed, adults and children should receive ceftriaxone or cefotaxime at meningitis doses, with addition of vancomycin in areas where penicillin resistance is prevalent. Clindamycin, levofloxacin, or moxifloxacin are alternates for patients with serious penicillin allergy. Children with a history of serious penicillin allergy should receive vancomycin plus levofloxacin.

Use of pneumococcal vaccine in patients at risk is especially important now that antimicrobial-resistant \textit{S. pneumoniae} is prevalent, but the efficacy of this vaccine in these patients is unclear. Persons with functional hyposplenism related to serious underlying diseases often respond poorly to pneumococcal vaccine. Asplenic people should be immunized against pneumococcus, \textit{H. influenzae} type b, \textit{N. meningitidis}, and influenza virus. Children should receive prophylaxis with oral penicillin or amoxicillin up to the age of 5 years and for at least 1 or 2 years after splenectomy (but this is not evidence-based), provided they have not had an invasive pneumococcal infection and have received pneumococcal immunizations. Long-term antimicrobial prophylaxis is generally not recommended in adults. These patients should have standby oral antibiotics at home (amoxicillin-clavulanate, levofloxacin, or moxifloxacin) with instructions to self-administer at the first sign of infection, and they should be provided with information and a medical alert bracelet. Fatal pneumococcal infection has occurred in patients immunized with pneumococcal vaccine who were also taking penicillin.

\section*{IMMUNOSUPPRESSIVE THERAPY}

\section*{Corticosteroids}

High doses of corticosteroids alter the distribution and function of neutrophils, monocytes, and lymphocytes. Corticosteroids suppress inflammation and enhance susceptibility to infection by impairing the mobilization and function of neutrophils and mononuclear cells at sites of primary lodgment of microorganisms in tissues. Corticosteroids inhibit neutrophil adherence to endothelium, decrease chemotaxis of neutrophils and monocytes, and inhibit phagocytosis and intracellular killing of microorganisms. Corticosteroids also severely impair CMI, probably a result of inhibition of the migration of lymphocytes to the site of antigen challenge, inhibition of lymphokine production, and consequent inhibition of lymphocyte proliferation. They also inhibit both classical and alternative pathways of complement activation. The hyperglycemia that occurs with corticosteroid use also contributes significantly to infection risk. Moreover, patients receiving high-dose corticosteroids have infection risks related to anatomic abnormalities of the underlying disease, treatment with other immunosuppressive agents, cancer chemotherapeutic agents, radiation therapy, and implantation of foreign bodies.

Acute administration of corticosteroids produces marked alterations in circulating leukocyte numbers. Basophils, eosinophils, and monocytes decrease, whereas neutrophils are increased. These changes occur within 4 to 6 hours and abate by 24 to 48 hours after a single steroid dose. There is a redistribution of lymphocytes, predominantly T cells, out of the circulation, resulting in lymphocytopenia. Acute or chronic corticosteroid therapy has little effect on serum immunoglobulin levels.

The most common infections occurring in patients receiving high-dose corticosteroids are those caused by pyogenic bacteria (\textit{S. aureus}, streptococci, and gram-negative bacilli). Despite the profound depression of CMI that occurs in patients taking corticosteroids, these patients generally have few infections commonly recognized as associated with defective CMI. The most common are tuberculosis and severe or disseminated infections caused by varicella-zoster and herpes simplex viruses. Patients receiving moderate doses of corticosteroids for asthma and other disorders are at increased risk for lethal primary varicella infection. Other infections seen with corticosteroid use include those caused by \textit{Listeria}, \textit{Salmonella}, \textit{Legionella}, \textit{Nocardia}, \textit{Candida}, \textit{Aspergillus}, \textit{Cryptococcus}, \textit{Histoplasma}, \textit{Coccidioides}, \textit{Pneumocystis}, \textit{Toxoplasma}, \textit{Cryptosporidium}, and \textit{Strongyloides}. Patients with neurologic diseases have much higher rates of infectious complications than do patients with intestinal, hepatic, or renal disease. The infectious complications related to corticosteroid use increase with doses of prednisone equivalents of more than 20 mg/day in adults, with total doses of more than 700 mg, and with treatment longer than 30 days. The risk of adrenal suppression can be decreased by use of prednisone doses less than 7.5 mg/day, administration of doses early in the day, avoidance of split doses, and use of alternate-day dosing.

Corticosteroids decrease leukocyte accumulation at inflammatory sites, and the whole cascade of responses leading to local manifestations of infection is slowed. These effects result in delayed presentation of serious infections. In addition, prolonged administration of corticosteroids results in delayed wound healing. For example, skin sutures should be left in place 50% to 100% longer than in normal patients. Short-term treatment has little effect on wound healing.

Use of corticosteroids greatly increases the risk of hospital admission for complications of diverticular disease. The diagnosis of peritonitis resulting from perforation of colonic diverticula, appendicitis, peptic ulcer, or another primary intra-abdominal condition is particularly difficult. These patients have abdominal discomfort, but they may have few abdominal findings and need rapid investigation for life-threatening abdominal disease. CT scan of the abdomen and pelvis and surgical consultation may be needed emergently in these patients. Broad-spectrum antimicrobials to cover for gram-negative enteric bacilli and anaerobes should be administered without delay.

Other complications unrelated to the effects on the immune system include iatrogenic Cushing’s syndrome, peptic ulcer disease, pancreatitis, benign intracranial hypertension (pseudotumor cerebri), psychosis, glaucoma, posterior subcapsular cataract, poor wound healing, sodium retention, hypertension, vascular thrombosis, hyperglycemia, diabetic ketoacidosis, hyperosmolar hyperglycemic state, avascular necrosis of bone (especially the femoral and humeral heads), myopathy, and osteoporosis, resulting in vertebral compression fractures and other spontaneous fractures. In addition, adrenocortical insufficiency may occur on withdrawal of therapy.

\section*{Other Immunosuppressive Medications}

Commonly used immunosuppressives include cyclosporine, tacrolimus, sirolimus, mycophenolate, azathioprine, methotrexate, and cyclophosphamide. They treat a wide variety of conditions,
including rheumatoid arthritis, psoriasis, nephrotic syndrome, and inflammatory bowel disease, and they are used in the prevention and treatment of organ transplant rejection. These drugs depress immune function, especially CMI. In addition, they have a narrow therapeutic window, wide-ranging toxic side effects, and many significant drug-drug and drug-food interactions. Patients may present for evaluation of symptoms caused by an adverse drug reaction or an infection. Before altering current medications, the physician needs to check carefully for drug interactions.

Immunomodulating agents are available for treatment of a variety of immune-mediated inflammatory diseases, including rheumatoid arthritis, psoriasis and psoriatic arthritis, ankylosing spondylitis, and inflammatory bowel disease. Some of these drugs include inhibitors of tumor necrosis factor alpha (infliximab, adalimumab, certolizumab, golimumab, etanercept), inhibitors of interleukins (tocilizumab, anakinra), inhibitor of pyrimidine synthesis (leflunomide), and inhibitor of T-cell activation (abatacept). These agents, particularly the tumor necrosis factor inhibitors, are associated with increased susceptibility to infection, particularly disseminated infection with various intracellular pathogens. Reactivation of latent infection with M. tuberculosis, nontuberculous mycobacterial infection, histoplasmosis, and coccidioidomycosis is frequently disseminated and extrapulmonary at presentation. Additional infections seen at increased frequency include cryptococcosis, listeriosis, legionellosis, salmonellosis, aspergillosis, candidiasis, and pneumocytosis. The clinician should be alert to unusual manifestations of infection in patients taking these agents as misdiagnosis and delayed diagnosis increase mortality. These drugs may also cause impaired wound healing, so skin sutures should be left in place for a longer time than is usual.

**KEY CONCEPTS**

- Immunosuppressed persons who present with acute infections, especially those that are neutropenic, may appear deceptively benign initially, their symptoms and signs often mimicking noninfectious complications, only to deteriorate rapidly if they are not evaluated and treated urgently. Early use of broad-spectrum antibiotics is indicated after obtaining appropriate cultures of all potential sites of infection, including intravascular catheters.

- Immunosuppressed patients can have serious local or systemic infections without fever, which may be manifested by unexplained tachypnea or tachycardia, mental status changes, metabolic acidosis, increased volume requirements, rapid changes in serum glucose or sodium concentration, or acute abdominal pain.

- In neutropenic cancer patients, most severe infections and almost all instances of bacteremia occur when the neutrophil count is less than 100 cells/mL.

- In neutropenic patients, the temperature should be measured orally or tympanically, not rectally.

- In neutropenic cancer patients, pneumonia and anorectal infection are more likely to be associated with bacteremia than other localized infections.

- Gram-positive organisms are responsible for most serious infections in neutropenic cancer patients, but infections due to gram-negative organisms are more rapidly lethal.

- Neutropenic cancer patients with chemotherapy-induced oral mucositis can develop rapid onset of fever with shock, acute respiratory distress syndrome and rash due to viridans streptococci.

- If the chest radiograph is normal or inconclusive but there is still suspicion for pneumonia, CT of the chest without contrast should be obtained because pneumonia is often detected by chest CT in febrile neutropenic patients with normal findings on the chest radiograph.

- Broad-spectrum intravenous antimicrobial therapy with cefepime, meropenem, imipenem, or piperacillin-tazobactam, should be initiated promptly in the febrile neutropenic patient, with an aminoglycoside added for the more seriously ill patient. Aztreonam plus vancomycin should be administered to those with serious penicillin-allergy. Empirical fluoroquinolone therapy should be avoided except for specific indications.

- Some low-risk febrile neutropenic patients may not require admission to the hospital, but can be managed in a short stay observation unit or be discharged home from the ED.

- Patients with cell mediated immune deficiency including those on high dose corticosteroids may develop life-threatening infections with intracellular bacteria (Listeria, Salmonella, tuberculosis), fungi (Cryptococcus, Coccidioides, Histoplasma), herpes simplex virus, and varicella-zoster virus.

- Patients with end stage renal disease on hemodialysis who develop pneumonia, C. difficile disease, or infections of dialysis access sites have high mortality.

- Functional or surgical asplenia predisposes to fulminating infection with pneumococci and other encapsulated organisms (H. influenzae, N. meningitidis, and Capnocytophaga canimorsus after dog bites) and, when seen early, may be misdiagnosed as a viral illness, gastroenteritis, or food poisoning.

- High doses of corticosteroids cause profound dysfunction of neutrophils and mononuclear cells and impair cell-mediated immunity (CMI), resulting in an increase in infections caused by pyogenic bacteria, varicella-zoster and herpes simplex viruses, tuberculosis, and a wide variety of other bacteria, fungi, and parasites.

CHAPTER 187: QUESTIONS & ANSWERS

187.1. What is the most common site of infection in febrile neutropenic patients?
A. Gastrointestinal tract
B. Perineum and anorectal area
C. Respiratory tract
D. Skin and soft tissue
E. Urinary tract

Answer: C. The respiratory tract is the most common site of infection, with 25% of infections in the lung and another 25% in the mouth or pharynx (and an additional 5% in the nose or sinuses). Still, all neutropenic patients with fever need to have a thorough physical examination because an undiagnosed infection can cause severe morbidity or mortality.

187.2. A 49-year-old diabetic male who has been receiving chemotherapy for non-Hodgkin’s lymphoma presents with fever and facial pain. Six weeks ago, he was treated with broad-spectrum antibiotics for fever but had negative cultures of blood and urine. He is taking ciprofloxacin as prophylaxis against infection. Examination is normal except for a purple-black lesion on his hard palate that looks like dried blood. A complete blood count shows severe neutropenia. In addition to blood cultures and chest radiography, what action should be taken immediately?
A. Administer intravenous clindamycin or ampicillin-sulbactam.
B. Administer intravenous levofloxacin.
C. Observe in the emergency department (ED) because he may be a candidate for home antibiotic therapy if other laboratory tests are normal, if he appears stable after an initial dose of antibiotics, and if his oncologist agrees.
D. Obtain a computed tomography (CT) scan of the paranasal sinuses and initiation of intravenous antifungal therapy in the hospital.
E. Undertake coagulation tests to check for a bleeding disorder induced by chemotherapy.

Answer: D. This patient has invasive aspergillosis or mucormycosis until proven otherwise. These fungi invade tissues and produce life-threatening necrotizing infections in cancer patients with neutropenia, as well as in diabetic patients, especially those who have received broad-spectrum antibiotics. CT scan will often show deep extension of the infection into the sinuses, orbit, or brain. The initial lesion in the palate or nose is often mistaken for a benign process. The antibiotics listed in A and B are incorrect. The
most appropriate empirical antibiotic regimen is cefepime or piperacillin-tazobactam, with or without an aminoglycoside, in addition to antifungal therapy. He is not a candidate for home therapy.

187.3. A 27-year-old male presents to the emergency department (ED) with acute onset of fever, chills, headache, myalgias, vomiting, mild abdominal cramping, and diarrhea for 8 hours. A splenectomy was performed 15 years earlier when he was treated for lymphoma, which has been in remission since then. He is not taking any medications and has been well. Vital signs are as follows: pulse, 125 beats/min; blood pressure, 110/60 mm Hg; respiratory rate, 20 breaths/min; and temperature, 39.5°C. His mental status is normal, and he has mild generalized abdominal tenderness. What is the most appropriate treatment for this patient at this time?

A. Blood cultures followed by immediate administration of ceftriaxone or cefotaxime, with or without vancomycin.

B. Hydration, antipyretic, antiemetic, and observation in the ED.

C. Immediate hospital admission with observation and frequent abdominal examinations.

D. Lumbar puncture.

E. Stool testing for occult blood and fecal leukocytes.

**Answer:** A. This patient is at high risk for overwhelming postsplenectomy sepsis, usually caused by *Streptococcus pneumoniae*. Persons who have undergone splenectomy for a hematologic disorder or lymphoma are at much higher risk for overwhelming postsplenectomy infection than are those undergoing splenectomy for trauma. The initial prodromal symptoms may be misdiagnosed as a viral illness, gastroenteritis, or food poisoning before there is abrupt deterioration with development of septic shock with disseminated intravascular coagulation, purpura, and multiorgan dysfunction. After blood cultures are obtained, he should immediately receive antimicrobials active against pneumococci, meningococci, and *Haemophilus influenzae*. He can be investigated for other possible etiologies of his symptoms after this initial critical action is taken.

187.4. Which answer is correct regarding diagnosis and management of patients on long-term high-dose corticosteroid therapy?

A. Acute, short-term administration of high-dose corticosteroids, but not long-term administration, can make the diagnosis of peritonitis particularly difficult.

B. After laceration repair, sutures should left in place for 50% to 100% longer than is usual.

C. Complications of chronic corticosteroid use include pancreatitis, pseudotumor cerebri, avascular necrosis of bone, cataracts, myopathy, spontaneous vertebral fractures, psychosis, and hypoglycemia.

D. Long-term corticosteroid use is frequently accompanied by peripheral blood neutrophilia.

E. Most serious infections in these patients are caused by organisms associated with defective cell-mediated immunity (CMI), such as severe or disseminated varicella-zoster and herpes simplex infections, tuberculosis, *Listeria*, *Cryptococcus*, and histoplasmosis.

**Answer:** B. Corticosteroids interfere with wound healing, so sutures need to remain in place longer than is usual for the type of laceration. Despite the profound defect in CMI that occurs with long-term corticosteroid use, infections with organisms associated with defective CMI are unusual. Most serious infections in these patients are caused by pyogenic bacteria, such as *Staphylococcus aureus*, streptococci, and gram-negative bacilli. Both short-term and long-term administration of corticosteroids interfere with the diagnosis of peritonitis. These patients will have poorly localized abdominal discomfort with minimal findings on examination. All the conditions listed in B are associated with chronic corticosteroid use—except hypoglycemia. Corticosteroid use is associated with hyperglycemia, hyperosmolar nonketotic diabetic coma, and diabetic ketoacidosis.
PRINCIPLES

Solid organ transplantation for end-stage renal, hepatic, cardiac, and pulmonary failure has made significant advances since the first successful kidney transplant in 1956. In 2009, over 29,000 kidney, liver, pancreas, heart, and lung transplants were performed. Because 1-year survival rates for all solid organ transplants exceed 80% and many patients survive much longer, increasing numbers of transplant patients are being seen in the emergency department (ED) with illnesses that can be complicated by their history of transplantation. Emergency clinicians should have a basic knowledge of organ transplant pathologies, an understanding of the initial approach to their management, and an appreciation of the utility of prompt consultation with transplant surgeons or oncologists.

Pathophysiology

Transplanted organs have surgical anastomoses to a variety of structures, including vessels, bronchi, ureters, intestines, and even the bladder. They are devoid of their native innervations and thus pain is an unreliable sign of underlying disease. Furthermore, the normal inflammatory and immunologic responses to infection and malignant disease are impaired. Subtle symptoms and signs may be the harbingers of serious complications, and each complaint merits careful investigation. Even in the most advanced stages of severe disease, patients may have few specific complaints and physical findings. The baseline physiologic capacity of the allograft will aid in interpretation of chief complaints in the context of possible organ failure. Subtle changes in allograft function may be a harbinger of an episode of rejection.

Transplant organ complications can generally be classified into one of four categories: anatomy, rejection, infection, and drug toxicity. The time since transplantation will help narrow the differential diagnosis; however, the exact etiology is often not determined until the patient is admitted to the hospital. It is also important to consider the risk of infection associated with immunosuppression and potential for drug toxicities when patients present with issues unrelated to their transplant.

Anatomy

Anatomic complications of solid organ transplants can be categorized into three groups: vascular, nonvascular anastomosis, and complications related to surgery. These are often manifested early in the post-transplantation course prior to initial discharge from the hospital, but delayed presentations can occur.

Vascular complications can include both arterial and venous structures, including thrombosis, stenosis, arteriovenous fistula, and pseudoaneurysm formation. Acute thrombosis of arteries may lead to fulminant organ failure. Arterial stenosis may also develop later in the course, with its effects typically determined by the degree of blood flow restriction. Pseudoaneurysms may develop and quickly lead to hemorrhagic shock if they rupture.

Nonvascular organ anastomoses may include bile ducts, bronchi, and ureters. Complications related to these structures include anastomotic leaks and obstructions from scarring, migration of stents, or stone development that may lead to acute graft dysfunction, infection, and abscess formation. Early identification is vital to salvage of the graft, and the evaluation includes laboratory investigation of graft function, cultures, imaging, and prompt consultation of transplant specialists.

Rejection

Rejection involves a complex set of T-cell receptor mediated pathways that lead to cytotoxic activity, B-cell memory and antibody formation, and cell death of the transplant allograft. Each transplant patient typically has a lifelong course of a waxing and waning immune response to the allograft, mandating ongoing surveillance of allograft function. Differentiation of infection and rejection is often difficult and the determination is often made only after biopsy of the transplanted organ or positive culture results are identified.

Rejection typically occurs in three phases: hyperacute, acute, and chronic. Hyperacute rejection occurs with preformed antibodies against major histocompatibility complex or ABO blood type antigens. It is rare with careful donor-recipient matching, and typically occurs in the immediate perioperative period. Acute rejection occurs over days to weeks after transplantation. The patient presents with constitutional symptoms and signs of transplant organ insufficiency. Expeditious laboratory assessment, imaging, and possible allograft biopsy can confirm the diagnosis of rejection. If immunosuppression is stopped, acute rejection may occur at any time.

Chronic rejection, now referred to as chronic graft dysfunction, has a time course of months to years and results in the gradual failure of the transplanted organ over time. Each organ presents slightly differently, with interstitial fibrosis and tubular atrophy causing dysfunction in kidneys; inflammation causing airway obstruction in lungs; fibrosis of bile ducts, veins, and arteries in liver; and arteriosclerosis, or chronic allograft vasculopathy (CAV) in the heart.

Infection

Infection is the primary cause of mortality after transplantation. Deaths from infection occur in 13% to 16% of kidney and heart transplants, 15% in liver, and 21% in lung transplants. Signs of infection in this population of patients are often blunted by immunosuppression. Vague complaints of malaise and fatigue or the chief complaint of a fever in an afebrile patient may herald a severe infection. Any new headache with or without visual changes may be the first symptom of meningitis or brain abscess. All transplant patients with fever should be aggressively evaluated. The diagnostic evaluation includes blood and urine cultures, computed tomography (CT) scan or ultrasound, and lumbar puncture. In addition, complete blood count, glucose
concentration, serum chemistries, blood urea nitrogen and creatinine concentrations, chest radiography, and electrocardiography are recommended. Aggressive management usually translates into increased patient survival and graft function. Broad spectrum antibiotics, antiviral agents, and antifungal medications should be considered, with awareness of nephrotoxicity and drug-drug interactions.

The timing of infection can be separated into three periods: first month after transplantation, between 1 and 6 months after transplantation, and more than 6 months after transplantation. These distinctions help predict the etiologic agents of the infection (Box 188.1).

**First Month After Transplantation.** The majority of infections occurring in the first month after transplantation are preexisting, donor derived, or nosocomial. Both donor and recipients undergo extensive serologic testing, but preexisting viral infections occurring in the first month after transplantation are VZV, varicella zoster virus.

Donor derived infections complicate about 1% of transplants, with the risk of transplant transmitted HIV infection reported to be 1 out of 5000. Bacterial transmission can occur, especially in transplant patients including bacteremia, ventricular-associated pneumonias, surgical site infections, and catheter-associated urinary tract infections.

**1 to 6 Months After Transplantation.** The period of 1 to 6 months after transplantation is a very high risk period for transplant patients. Infections occurring during this time are divided into two general types: immunomodulating viral infections and opportunistic infections.

Cytomegalovirus (CMV) is the most important and prevalent immunomodulating viral infection during this period. It may be asymptomatic; manifest as fever, malaise, and leukopenia; or present with symptoms specific to invasive disease of the lungs, liver, or gastrointestinal (GI) tract. CMV pneumonitis presents with fever, hypoxia, and diffuse infiltrates on chest x-ray. CMV GI disease causes ulcerations that can present with abdominal pain, diarrhea, bleeding, or perforation. CMV hepatitis can present with microabscesses in the liver. Definitive diagnosis is made by bronchoalveolar lavage or biopsy of lung, intestine, or liver, and patients often need admission for intravenous (IV) ganciclovir.

Furthermore, CMV has been shown to have multiple negative indirect effects in the solid organ transplant patient because of its immune-modulating properties, including increased risk of bacterial and fungal infections, opportunistic infections, acute or chronic organ rejection, and even increased mortality. CMV has been linked to glomerulopathy and graft dysfunction in renal allograft recipients, recurrent HCV in liver transplantation, and acute cardiac dysfunction and accelerated coronary artery atherosclerosis in heart transplants.

With the advent of prophylaxis for CMV disease, the average risk of CMV disease has decreased from 30% to 12%. Most transplant centers employ prophylactic therapy with valganciclovir for high risk patients for 3 to 6 months. Future research is focused on effective CMV vaccines, which are currently in phase II clinical trials. Epstein-Barr virus is another significant immune-modulating virus that causes infections during the first 4 months of transplant. Epstein-Barr virus infection may cause a mononucleosis-like syndrome (fever, malaise, pharyngitis, lymphadenopathy), or hepatitis, pneumonitis, and GI complaints. The other feared complication of Epstein-Barr virus is post-transplant lymphoproliferative disorder (PTLD), which can present in varying ways including a viral mononucleosis syndrome, plasmacytic hyperplasia, B-cell infiltration of organs, or lymphoma. Treatment depends on type and extent of PTLD but includes reduction in immunosuppression, monoclonal B-cell antibody therapy (rituximab), and cytotoxic chemotherapy.

BK virus is a polyomavirus that is common and asymptomatic in high risk subjects but pathologic in solid organ transplant patients. BK virus resides in the kidneys, and it can progress from viruria to viremia to nephropathy, graft dysfunction, and graft loss in renal transplants. There have also been case reports of BK nephropathy in heart, lung, and pancreas transplants. Diagnosis is by urine or serum viral loads and biopsy, and patients typically require reduction in immunosuppression to treat the disease.

Hepatitis B and C may recur after transplantation. Hepatitis B–positive donors are being used more frequently now that prophylaxis with lamivudine, tenofovir, or entecavir are effective. Hepatitis B reactivation usually presents mildly with fatigue, malaise, jaundice, and elevation in serum transaminases, but it causes fulminant hepatitis in 12% to 20% of cases with cholestasis, hypoprothrombinemia, and rapid deterioration.

Other viral infections such as human herpes virus 6, primary varicella zoster virus infection, or reactivation of varicella zoster virus with shingles are common in transplant patients. Primary varicella infection may be life threatening with pneumonia, pancreatitis, hepatitis, encephalitis, and disseminated intravascular
coagulation. Treatment includes IV varicella-zoster immune globulin and IV acyclovir. Reactivation varicella zoster virus is usually confined to a single dermatome. Facial zoster involving the cornea and disseminated infections in more than one dermatome are indications for admission, although consultation with a transplant specialist for any episode of shingles is advised.4

Opportunistic pathogens in this time period are more common given the high level of immunosuppression. Listeria typically presents with fever, abdominal pain, and diarrhea in the immunocompetent patient, but it may cause bacteremia and meningoencephalitis in the solid organ transplant patient.15 Treatment includes high dose penicillin or ampicillin and an aminoglycoside, although nephrotoxicity must be considered.

Nocardia infection is highest in lung and heart transplant patients and lower in kidney and liver transplant recipients. It typically presents with fever, cough, dyspnea, and hemoptysis, but it can progress to disseminated infection with central nervous system (CNS) abscess, skin and soft tissue abscess, osteomyelitis, or septic arthritis. Nocardia may be seen on gram stain as classic beading and branching gram-positive bacilli, although culture can take weeks. First line treatment is usually with trimethoprim-sulfamethoxazole (TMP-SMX), although other options include minocycline, amikacin, imipenem, cefotaxime, and ceftriaxone.15

Mycobacterial disease may manifest as opportunistic reactivation or a primary infection. Immunosuppressed solid organ transplant patients may not present with classic pulmonary tuberculosis, although they can present with cavitary or military tuberculosis (Fig. 188.1). They may present with nonspecific systemic symptoms, meningitis, peritonitis, pericarditis, liver abscess, renal tuberculosis, or disseminated disease. Treatment is complex because of drug interactions and graft dysfunction; however, it usually includes isoniazid (INH) with or without rifampin and ethambutol or pyrazinamide.16

Invasive candidiasis can present with fungemia, urinary tract infection, peritonitis, pleural empyema, or intra-abdominal abscess. Aspergillosis most frequently presents in the lungs as pulmonary nodules with or without cavitation but may disseminate to any organ system, including the CNS. Treatment is with antifungal agents, such as amphotericin B, azoles (fluconazole, voriconazole), or echinocandins (caspofungin, micafungin).4

Endemic mycosis such as histoplasmosis, blastomycosis, and coccidioidomycosis should be considered based on geographic location and exposure, although histoplasmosis is the most commonly reported.17 They all typically manifest with fever and respiratory symptoms and varying infiltrates on chest radiographs. Amphotericin B is usually first line therapy.

Pneumocystis jiroveci (carinii) pneumonia manifests subacutely with fever, nonproductive cough, progressive dyspnea, and an interstitial infiltrate on the chest radiograph (Fig. 188.2). Fortunately, its incidence is reduced with prophylactic low-dose TMP-SMX. Differentiation from CMV pneumonia is difficult without bronchoscopic confirmation. Treatment of Pneumocystis pneumonia includes IV TMP-SMX and steroids, depending on the degree of hypoxia.

Toxoplasmosis can occur as primary infection, but more commonly it is a reactivation of latent infection, resulting in pneumonia, hepatosplenomegaly, myocarditis, brain abscesses, or diffuse encephalitis. Typically, treatment of toxoplasmosis is a combination of IV sulfadiazine and pyrimethamine, although TMP-SMX has been used with some success in acquired immunodeficiency syndrome (AIDS) patients. Cryptococcus neoformans may present in the intermediate or late period in solid organ transplant patients. Patients may present with meningoencephalitis and up to one-third have lesions apparent on imaging. Diagnosis is confirmed by lumbar puncture or serum cryptococcal antigen. Initial therapy is with amphotericin B and flucytosine.

Strongyloides stercoralis is an intestinal nematode that can present with hyperinfection syndrome, causing a necrotizing hemorrhagic enterocolitis and hemorrhagic pneumonia. Disseminated strongyloidiasis causes severe abdominal pain, obstructive symptoms, hemorrhage and secondary peritonitis, sepsis, meningitis, and pneumonia. Treatment of disseminated strongyloidiasis is with thiabendazole, although mortality approaches 70%.

Each transplant center will have different prophylaxis guidelines, but overall prophylaxis with TMP-SMX for pneumocystis pneumonia (which also covers Nocardia, Listeria, and urinary tract infections), fungal prophylaxis with fluconazole, and CMV prophylaxis with ganciclovir when indicated have decreased the effect of classic opportunistic offenders.

6 Months After Transplantation

Six months after organ transplantation, solid organ transplants can be categorized into three groups relative to infection

Fig. 188.1. A 22-year-old man with a kidney transplant who presented with fever and a cough was diagnosed with reactivated tuberculosis by sputum analysis.

Fig. 188.2. A and B, Bilateral perihilar and lower lobe alveolar infiltrates in a cardiac transplant recipient from Pneumocystis jiroveci. (From Tewari S, Maurer J: Pulmonary considerations of organ transplantation. In Gines LG, Cosimi AB, Morris PJ, editors: Transplantation, Malden, MA, 1999, Blackwell Science, p 617.)
susceptibility: healthy transplant, chronic viral infection, and chronic rejection.

**Healthy Transplant.** Healthy transplant patients have no chronic immunomodulating viral infections and a functioning allograft; they are maintained with low doses of immunosuppressant medications. They have a mildly increased susceptibility to normal community-acquired infections, such as influenza, urinary tract infection, and pneumococcal pneumonia.

**Chronic Viral Infection.** Progressive disease may develop as a result of the combination of viral immunomodulating infections and long-term immunosuppression. Hepatitis B and C may cause progressive liver disease or hepatocellular carcinoma (HCC). CMV may present in this time period after prophylaxis is discontinued. Epstein-Barr virus–associated PTLD can occur late as well. Herpes simplex virus (HSV) reactivation is common after solid organ transplantation and can be manifested as oral or anogenital lesions, more often ulcers than vesicles.

**Chronic Rejection.** Patients with chronic rejection require ongoing aggressive immunosuppressive treatment to protect the allograft and are at higher risk of late infections. These patients are at the highest risk for life-threatening opportunistic infections, as well as standard nosocomial infections.

**Drug Toxicity**

Immunosuppressive therapy requires correctly timed drug combinations to establish a delicate balance between immunosuppression, rejection, and susceptibility to infection. Regimens are transplant center specific, but most include a calcineurin inhibitor, an antimitabolite, and varying dosages of steroids. Recognition of the side effects, toxicities, and potential drug interactions of immunosuppressant medications is an important component in the care of any transplant patient (Table 188.1).

*Appropriate levels vary based on time since transplantation, level of rejection, and concurrent toxicity and medications. CBC, Complete blood count; GI, gastrointestinal.
The side effects of cyclosporine can be severe, with the most important being nephrotoxicity. Cyclosporine causes renal tubular injury and direct renal artery vasospasm in a dose-dependent manner, leading to systemic hypertension in many recipients. This is especially precarious when used with other drugs typically used after transplantation, such as amphotericin B, aminoglycosides, and high-dose TMP-SMX. Cyclosporine can also cause hepatotoxicity, hyperlipidemia, hyperuricemia, hyperkalemia, hirsutism, tremor, and gingival hyperplasia. Rarely, cyclosporine toxicity can result in a neurotoxic syndrome of seizures, confusion, cortical blindness, and quadriplegia, progressing to coma if left untreated.

Cyclosporine levels are altered by many common post-transplantation medications (Table 188.2). Drugs that inhibit cytochrome P₄₅₀ metabolism, such as erythromycin and ketoconazole, produce elevated cyclosporine levels and enhanced toxicity. Drugs that upregulate cytochrome P₄₅₀ may decrease cyclosporine levels and possibly trigger episodes of organ rejection.

Tacrolimus. Tacrolimus is a macrolide compound that binds to lymphocyte proteins and inhibits cytokine synthesis. Although it is chemically different, it has similar biological properties to cyclosporine. Because of an improved side effect profile and more effective immunosuppression, tacrolimus is used more frequently than cyclosporine as either primary or rescue therapy for allograft rejection.

Tacrolimus can cause nephrotoxicity, as well as neurotoxicity. In combination with steroids, tacrolimus can lead to hyperglycemia and diabetes. Tacrolimus can also cause anorexia, diarrhea, dyspepsia, and nausea. Macrolide antibiotics should not be prescribed to patients receiving tacrolimus because they augment tacrolimus levels.

Mammalian Target of Rapamycin Inhibitors. Sirolimus and everolimus are two drugs in the mammalian target of rapamycin (mTOR) class. mTOR is key in the pathway for T-cell clonal activation.

Sirolimus was originally used as an anti-fungal agent but was later found to have immunosuppressive and antiproliferative properties. Initially, there was great hope for sirolimus in reducing risk of malignancy in solid organ transplants; however, results have been mixed. Sirolimus has shown promise in reducing mortality in liver transplants with HCC and some benefit in decreasing vasculopathy in cardiac transplants. Important side effects include nephrotoxicity and delayed wound healing, especially when used with cyclosporine. Other side effects include hyperlipidemia, anemia, thrombocytopenia, proteinuria, stomatitis, and diarrhea.

### Antimetabolites

**Azathioprine.** Azathioprine is an antimetabolite derivative of 6-mercaptopurine. One of the first immunosuppressive drugs for solid organ transplants, azathioprine inhibits both deoxyribonucleic acid and ribonucleic acid synthesis, resulting in a suppression of lymphocyte proliferation. Azathioprine works as a bone marrow toxin, so patients may exhibit dose-related neutropenia. Hepatic dysfunction and other GI disturbances may also occur.

**Mycothenolate Mofetil.** Mycothenolate mofetil (MMF) is an immunosuppressive agent with potent and selective inhibition of lymphocyte proliferation, so it has largely replaced azathioprine. It reduces the incidence of acute rejection, but it does not significantly improve long-term survival of transplant recipients or their allografts.

MMF has the advantage of a low side effect profile. The mostly mild effects resulting from its GI and hematologic toxicity include abdominal pain, nausea, diarrhea, gastrointestinalitis, leukopenia, and thrombocytopenia. Because magnesium and aluminum antacids interfere with the absorption of MMF, care should be exercised in treatment of the GI symptoms.

### Corticosteroids

Corticosteroids have a wide range of effects on the immune system, specifically the T lymphocytes. Because of the significant long-term toxic effects associated with chronic glucocorticoid administration, every effort is made to minimize glucocorticoid use.

Long-term corticosteroid therapy causes osteoporosis, cataracts, GI bleeding, glucose intolerance, skeletal myopathy, bone disease, and adrenal suppression (Fig. 188.3). Acute administration may lead to glucose and electrolyte abnormalities, as well as altered mental status. Acute withdrawal or severe illness may lead to an Addisonian crisis.

### SPECIFIC DISORDERS

#### Heart Transplant

In 2009, 2241 heart transplants were performed in the United States. The overwhelming majority of heart transplants are performed for cardiomyopathy and coronary artery disease, with less common reasons being congenital heart disease, valvular pathology, or retransplant. The 1-, 5-, and 10-year graft survival rates for heart transplants are reported to be 88.6%, 73.1%, and 53%, respectively. Infection and rejection are the leading causes of mortality in the first year, with overall causes of mortality being graft failure (22%), infection (14%), malignancy (14%), cardiac allograft vasculopathy (CAV; 10%), multiorgan dysfunction (10%), acute rejection (4%), and renal failure (4%). In one study of 131 ED visits by heart transplant patients, the most common complaints were fever (37%) and shortness of breath (13%), and 60% of the patients were admitted.

#### Anatomic Considerations

The majority of orthotopic (same anatomic site of the original organ) heart transplants now being performed in the United States are bicaval, where there is a single left atrial anastomosis,
two caval anastomoses, and aorta and pulmonary artery anastomoses. The other method of orthotopic heart transplantation is biastral, where the recipient right atrium connected to the vena cava is left intact, so the right and left atria, aorta, and pulmonary artery are anastomosed (Fig. 188.4).29

The transplanted heart is denervated, which causes clinically important physiologic changes. Without parasympathetic tone, the resting heart rate in a transplant patient varies from 95 to 110 beats/minute. Medications affecting the autonomic nervous system, such as atropine for bradycardia, will not have an effect on the denervated heart.29 The transplanted heart rate can increase with exercise or stress through the effects of endogenous catecholamines, up to 70% of the maximum heart rate for age, and exogenous pressor agents are effective in the transplanted heart. Upregulation of beta-adrenergic receptors appears to occur in the graft, with a slightly enhanced response to norepinephrine and isoproterenol. Beta-blockers can worsen autonomic dysfunction and exercise tolerance, so they are typically avoided in treating hypertension in post-transplant patients but may be used to treat acute supraventricular tachyarrhythmias.30,32 The transplanted heart is sensitive to adenosine, so the dose should be reduced by half. Lastly, heart transplant recipients often do not experience classic anginal symptoms with ischemia, but rather they have silent myocardial infarctions or present with heart failure symptoms or sudden cardiac death.

The most common electrocardiogram (ECG) abnormalities after heart transplant are incomplete right bundle branch block (RBBB), and repolarization abnormalities, although these changes are not felt to be of clinical significance. With the biastral technique, the electrocardiogram may demonstrate 2 P waves (one from the native recipient sinus node and one from the donor sinus node; Fig. 188.5). The PR, QTc, and QRS intervals are usually normal. Patients with symptomatic bradycardia should be admitted and may need pacemaker implantation. New onset tachyar-rhythmias (aflutter and atrial fibrillation) are concerning for potential rejection or CAV.25 Most heart transplant patients with brady or tachyarrhythmias should be admitted for further evaluation and management.

**Rejection**

Etiologies of acute rejection include medication noncompliance, drug-drug interactions, or concurrent CMV infection. Approximately 25% of heart transplant patients will have an acute rejection episode between initial hospital discharge and 1 year, and the risk is highest in the first 3 months.29,30 Acute rejection is often asymptomatic, although patients may present with fatigue, fever, dyspnea, signs of heart failure, or hypotension. Dyspnea is one of the most sensitive clinical criteria for rejection, so this complaint must be taken seriously. Other rare presentations of acute rejection are pericardial effusions or atrial arrhythmias.

Appropriate diagnostic tests include electrocardiogram, complete blood count, electrolytes, creatinine, troponin, cultures, chest x-ray, and echocardiogram, if possible. Patients who present with signs and symptoms concerning for acute rejection should be admitted for further evaluation and care. Endomyocardial biopsy is the gold standard for diagnosing acute rejection, and grading and treatment regimens are based on the results.32 Patients must follow a strict regimen of endomyocardial biopsies at decreasing intervals to monitor for rejection. A new blood test to monitor for rejection with gene expression profiling of leukocytes (AlloMap) has some promise, although use varies based on transplant center.

Acute rejection is treated with IV corticosteroids with or without OKT3 or ATG. If antibody mediated rejection is diagnosed, treatment also includes plasmapheresis, IV immunoglobulin, or adjuvant therapy with the anti-CD20 monoclonal antibody, rituximab (Rituxan).

CAV is associated with chronic rejection, immunosuppressant toxicities, and CMV infection and is a major determinant of morbidity and mortality for heart transplant patients. It is seen in 40% to 50% of transplants at 5 years. CAV is diagnosed via cardiac angiography with characteristic diffuse, concentric narrowing of coronary arteries rather than the eccentric focal narrowing caused by classic cardiac atherosclerosis. Like acute rejection, CAV is often asymptomatic, but it may present with new onset heart failure, myocardial infarction, arrhythmias, or sudden cardiac death. The only definitive treatment for documented CAV is retransplantation, so focus is on prevention with traditional risk factor management (hypertension, hyperlipidemia, diabetes mellitus [DM], obesity) and early recognition. mTOR inhibitors (such as, everolimus and sirolimus) have exciting implications for cardiac transplantation, including prevention of CAV and withdrawal of cyclosporine in setting of renal toxicity without increased risk of rejection.24,25,30

**Drug Toxicity**

Calcium channel blockers and amiodarone can increase cyclosporine, tacrolimus, or sirolimus levels. Statins have increased drug levels when taken concurrently with cyclosporine, so the statin side effects of rhabdomyolysis and myopathy may be seen.

**Infection**

Infections are a major cause of mortality in the first year after transplantation. Bacterial pneumonias, urinary infections, herpes virus infections, and invasive fungal infections have been noted as the most common infections in heart transplants.4 Mediastinitis is a feared complication of heart and lung transplant patients. It is usually caused by staphylococci, although aspergillus and...
**Nocardia** are important opportunistic infections. Toxoplasmosis is more common in heart transplant patients, because the organism may be encysted in the myocardium of donor. Chagas’ disease is an important reason for heart transplantation in South America, and about one-fourth of patients with Chagas’ pre-transplantation will undergo reactivation and acute disease. Reactivation can be asymptomatic or may cause myocarditis, subcutaneous nodules, or disseminated disease. Treatment is with benzimidazole. Because of the attendant risk of endocarditis, antibiotic prophylaxis should be provided for invasive procedures likely to cause bacteremia.

**Liver Transplant**

In 2009, 6320 liver transplants were performed in the United States. Unfortunately, 12,454 patients were on the transplant waiting list, and the waiting list mortality exceeds 20%. The most common indication for liver transplant is hepatitis C infection. Liver transplants have 1-, 5-, and 10-year graft survival rates of 85%, 67%, and 51%, respectively. Complications are common, and loss of function of the graft organ is rapidly life-threatening. In one study of over 1200 solid organ transplant patients presenting to the ED, liver transplant patients most commonly presented with abdominal pain or GI symptoms, infections were the most common ED diagnosis, and 67% were admitted to the hospital.

**Anatomic Considerations**

The orthotopic liver transplant (OLT) is connected to its host through five anastomoses (Fig. 188.6). The vessels are connected first, then the biliary system is reconstructed and often stented with a T-tube to prevent stenosis. The T-tube is left in place for up to 3 months. Anatomic complications are related to anastomosis and graft function. Hepatic artery thrombosis (HAT) is the most common vascular complication and is devastating, because it is the only arterial blood supply to the transplanted liver. Patients usually present during the first month of transplantation with jaundice, right...
Fig. 188.5. A 68-year-old man status post heterotopic heart transplantation; native heart rate of 55 beats/minute and donor heart rate of 75 beats/minute.
upper quadrant pain, and fever associated with elevated liver enzymes and bilirubin. Diagnosis is made by Doppler ultrasound, helical CT scan, or arteriography. HAT can cause graft dysfunction, bile necrosis leading to leaks, abscess formation, and sepsis. Treatment involves thrombectomy, either surgical or via interventional radiology.

Hepatic artery rupture is uncommon. It is usually caused by bacterial arteritis, and patients will present in hemorrhagic shock. Portal vein thrombosis occurs in up to 3% of liver transplants. When acute, it presents as graft failure with encephalopathy and refractory ascites. Later presentations include portal hypertension and its sequelae.

Biliary complications including leaks, obstruction, and strictures are additional anatomical complications. Leaks will present with abdominal pain and peritonitis. Obstructions may be caused by migrating stents or stone formation. Diagnosis is made with ultrasound or CT imaging. ED care should involve broad spectrum antibiotics (gram-positive, negative, and anaerobe coverage) and early consultation, because definitive care often requires percutaneous drainage or surgical intervention. Biliary strictures present within the first 6 months with a cholestatic picture. The vast majority are treated with endoscopic dilatation and stenting, although 18% to 30% of patients will have a recurrence.

**Rejection**

Acute rejection occurs frequently despite immunosuppressive therapy, with 60% to 80% of patients experiencing at least one episode. Rejection often begins 1 or 2 weeks after surgery, with fever, right upper quadrant pain, malaise, and elevated bilirubin and transaminase levels. Leukocytosis may occur but is nonspecific. Related conditions that simulate graft rejection are mechanical biliary obstruction, infection, ischemia from thrombosis of vascular anastomoses, viral infections, drug toxicity, and recurrent primary disease. Definitive diagnosis is made by allograft biopsy.

As soon as transplant rejection is suspected, hospitalization and treatment with high-dose methylprednisolone and optimization of immunosuppression should begin. If steroids fail, OKT3 monoclonal antibodies are used in addition to polyclonal antilymphocyte globulin. Treatment is usually successful, with 90% of patients responding to corticosteroids.

Chronic rejection occurs in up to 4% of liver transplant patients. Chronic rejection may be asymptomatic early on, or present with a more indolent course of features similar to acute rejection including malaise, jaundice, right upper quadrant pain. Laboratory investigations show elevated transaminases, and diagnosis is made by biopsy. Although chronic rejection may not respond to increases in immunosuppression, some centers may switch to tacrolimus, increase the dose, or add a third agent.

**Drug Toxicity**

The most common cause of renal failure after liver transplant is calcineurin inhibitor toxicity. In the event of worsening renal dysfunction, calcineurin inhibitor doses may need to be reduced or treatment changed to MMF or sirolimus. Over 75% of centers are using tacrolimus and MMF, and only 30% of patients require ongoing corticosteroids beyond 1 year after transplant. As with any transplant, careful consideration of drug-drug interactions must be made before prescribing new medications.

**Infection**

Patients with liver transplants have a higher incidence of infection than those with kidney or heart transplants, with the most common source being abdominal and biliary tract infections. Bacterial infections and sepsis are common given the severity of illness pre-transplant, and over 50% occur within the first 2 weeks. Patients presenting with abdominal pain in the first month should undergo laboratory evaluation, culture, and imaging to evaluate for cholangitis, peritonitis, liver abscesses, and abdominal abscesses. These are most commonly caused by gram-negative enteric bacilli, enterococci, and anaerobes, although staphylococcus and candida can also be culprit agents.
OLT patients are particularly susceptible to fungal infections; candida is most common, but invasive aspergillosis occurs in up to 8% of patients.4

Hepatitis B and C are issues in the long term for liver transplant patients. Hepatitis B virus (HBV) infection may occur with hepatitis B surface antigen (HBsAg) positive or HBV naive recipients. Graft refection by HCV positive recipients is almost certain. Treatment with interferon alpha and ribavirin may be successful in delaying fibrosis in some patients, although 10% to 30% of HCV positive recipients develop cirrhosis in 5 years.29

Kidney Transplant

Kidney transplants have the most successful survival rates of the solid organs. The 1-, 5-, and 10-year graft survival rates are reported to be 92%, 70%, and 43%, respectively.4 Due to increased survival rates and improved immunosuppressive pharmacotherapy, both the numbers of living transplant recipients and those waiting for transplants continue to grow. To address a chronic shortage, kidneys from older donors, those with a previous hepatitis, and even those with acute kidney injury have been used to increase the donor pool.40

Anatomic Considerations

The location of the transplanted kidney is most commonly in the iliac fossa. Donor renal vessels are anastomosed to recipient iliac vessels, and the donor ureter can be anastomosed directly to the recipient’s bladder or native ureter, with J stents left in place for 6 weeks. Vascular complications such as bleeding and thrombosis can occur. A hematoma can form up to a week after the procedure and cause urinary obstruction and hydronephrosis. Renal artery and vein thrombosis is less common but will present with oliguria, anuria, and rising creatinine. Late vascular complications are due to arterial stricture or stenosis. Ureteric complications occur in up to 15% transplants and include ureteric leak, stent migration, or stricture.41 Doppler ultrasound of the transplanted kidney can often identify anatomic issues with the allograft.

Infection

The most common source of infection is the urinary tract and is most commonly caused by Escherichia coli. Atypical pathogens such as urinary tract tuberculosis, mycobacteria, salmonella, and adenovirus can lead also to cystitis and graft failure.42 The use of prophylactic TMP-SMX has been shown to decrease the incidence of pyelonephritis in these patients.4 Oral antibiotics are adequate to treat patients with uncomplicated cystitis.

Graft pyelonephritis occurs in up to 13% of renal allograft patients. Patients with graft pyelonephritis may present with rigors, fevers, and pain over the implant site, although acute rejection may present similarly. Ultrasound should be performed to exclude partial obstruction in the early postoperative patient and in patients with incomplete bladder emptying, nephrolithiasis, or recurrent infections. Blood and urine cultures should be obtained routinely. Patients with graft pyelonephritis are typically admitted for treatment with IV antibiotics.

Chronic viral infections are important determinants in morbidity. BK nephropathy occurs in up to 10% of renal transplant patients.43 HCV is a common cause of recurrent and chronic infection in renal transplant patients, with liver disease developing in approximately 50% of seropositive patients.4

Rejection

Acute rejection is a common complication of kidney transplantation, with 1-year rates of 10% to 11% and an associated reduced graft survival.44 Clinically, renal graft rejection is manifested with fever, hypertension, edema, tenderness over the allograft, and decreased urine output. A subtle rise in serum creatinine concentration should prompt great concern. Renal ultrasound examination with color flow Doppler study should be performed to rule out obstruction, abscess, vascular thrombosis, and perirenal collections of blood, pus, or lymph. Early consultation with the transplant nephrologist is prudent, and definitive diagnosis is made with biopsy. Treatment is with high-dose IV methylprednisolone, with or without plasma exchange if antibody mediated rejection is suspected.45

Chronic transplant rejection occurs after long-term loss of adequate function due to nephrosclerosis or fibrosis of the blood vessels. This process involves proliferation of the vascular intima of renal vessels with marked decrease in the lumen size. Systemic hypertension ensues as the graft fails from ischemia, with resultant tubular and glomerular atrophy. Chronic allograft nephropathy is caused by immune and non-immune mechanisms and presents with proteinuria, hypertension, and graft dysfunction.

Lung Transplant

Although lung transplantation is still rare due to lack of donor tissue availability, it is increasing in frequency; more than 1600 are performed annually in the United States.4 Common indications include chronic obstructive pulmonary disease, cystic fibrosis, and pulmonary fibrosis. There has been a shift from single to double lung transplantation due to its impact on long-term outcomes and quality of life. Although there is compelling data documenting the beneficial impact of lung transplantation on functional status and hemodynamics, the data are less convincing for a survival benefit.46 Survival rates for lung and heart-lung transplant lag behind the other solid organ transplants with a 1-year graft survival of 80% and 89% and patient survival of 82% and 90%, respectively.

Anatomic Considerations

Single or bilateral lung transplantation requires anastomosis of the main bronchi, pulmonary veins to left atrium, and pulmonary arteries. Any of these anastomoses may break down and cause ischemia, prolonged air leak, or mediastinitis.47 Bronchial anastomatic complications such as stenosis, tissue degeneration, and dehiscence can also occur in up to 15% patients. Acute pleural complications and reperfusion edema can be seen within 1 week of transplant. Pneumothorax, hemothorax, pleural effusion, empyemas, and persistent air leaks can occur in roughly 20% of patients.

Rejection

Approximately 25% of lung transplant patients will have acute rejection in the first year.4 An episode of acute rejection can occur early as a few days after transplantation and as late as several years after. Clinically, the patient presents with cough, dyspnea, fatigue, and fever. Rales and rhonchi are heard, with deterioration in oxygenation and pulmonary function. Early rejection is often accompanied by infiltrates on the chest radiograph. When rejection occurs more than a month after transplantation, 75% of radiographs are normal or unchanged. The diagnosis of rejection is made by transbronchial biopsy showing lymphocytic infiltration. Suspected episodes of acute rejection are treated with high-dose corticosteroid therapy with OKT3 in refractory cases.

Chronic lung transplant rejection is caused by scarring or fibrosis of the airways and prolonged deterioration of lung function. Chronic rejection usually results from repeated infection and episodes of acute rejection, and it is a leading cause of late
morbidity and mortality. On pathologic examination, vascular sclerosis and progressive limitation to airflow occur from obliterator bronchiolitis. Rejection can occur several years after transplantation, but the mean time to onset is 8 to 12 months. Clinically, this rejection mimics an upper respiratory infection or bronchitis. If dyspnea is a component of the presenting complaint, a search for transplant rejection should be initiated. Chronic rejection is treated with high-dose corticosteroids. Antilymphocyte antibodies are used as well, but relapse of the rejection episode is common.

Infection
Infections account for up to 20% deaths in lung transplant patients. Transplanted lungs are highly susceptible to pneumonia, because they can be colonized by bacteria during the ventilator stage of the brain-dead donor. After transplantation, diminished mucociliary clearance, decreased cough reflex due to denervation, and defective function of alveolar macrophages are present. The most common infections are caused by gram-negative bacteria such as *Pseudomonas* and by *Staphylococcus aureus*. Influenza and respiratory viruses are the major cause of morbidity and mortality for lung transplant patients.

Antibiotic and antiviral therapy should be aggressively directed toward any pathogenic bacteria or virus cultured from the tracheobronchial tree.

CMV pneumonia is the most common opportunistic pulmonary infection after lung transplantation. Patients are at highest risk between 3 weeks and 4 months. Clinically, CMV infection closely resembles transplant rejection, so tissue biopsy and culture are required to differentiate the two entities. Treatment with an antiviral agent such as ganciclovir is effective but is often required long term (>12 months). Colonyization by *Candida* is common, but invasive diseases with *Aspergillus* and *Candida* provides the most significant fungal threat to the transplanted lung. Invasive species can cause bronchiolitis obliterans syndrome by inflammation and obstruction of the bronchioles, which increases the risk of graft failure. Although reactivation of tuberculosis is rare, pulmonary non-tuberculosis mycobacterial infections are relatively common.

Pancreas Transplant
Approximately 1300 pancreas transplant operations are performed in the United States annually, singly or in combination with a kidney. Pancreas transplants typically occur secondary to long-standing diabetes. Isolated pancreatic transplants have a high complication rate, with 1-year graft survival rates as low as 72%. Pancreas transplants have better outcomes, with a 1-year graft survival rate of 93%, and a 1-year patient survival rate of 96%.

Islet cell transplantation is under investigation as a treatment of diabetes mellitus. Although the procedural complication rate is significantly less compared with a whole pancreas transplant, islet transplantation requires several donors for adequate islet cell mass to achieve insulin independence. In addition, there is an increased attrition of islet graft function that occurs during the first few years compared with whole pancreas transplantation. These factors have made whole pancreas transplantation the most commonly performed type of beta cell replacement therapy.

Anatomic Considerations
Pancreas transplant surgeries vary widely based on surgeon and institution. Arterial perfusion is usually via the iliac vessels, venous revascularization may be systemic or portal, and exocrine function may be drained into the small intestine (80%) or bladder (20%). When drained into the bladder, patients develop a chronic non–anion gap acidosis caused by loss of bicarbonate into the bladder. Vascular thrombosis can be seen very early after transplant, typically within the first 48 hours. This is usually due to venous thrombosis of the pancreatic portal vein. Bleeding at the anastomotic site can result in an intra-abdominal hematoma. Pancreatitis is expected but should be closely monitored. Duodenocystostomy fistulas may form in the early post-transplantation period. Intra-abdominal abscess may form anytime but most commonly 1 to 6 months post-transplant. The clinical findings are abdominal pain, tenderness, hyperamylasemia, leukocytosis, and elevated serum creatinine.

Rejection
One year acute rejection rates for pancreas transplant have been reported from 16% to 25%. Early acute pancreatic transplant rejection occurs when exocrine cell function is compromised. Patients present with pain around the graft due to peritoneal irritation. Serum lipase, amylase (or urinary amylase if patients are bladder drained), will be elevated. Destruction of beta cells occurs late, following injury of exocrine tissue; therefore, hyperglycemia is a late and often irreversible finding. The gold standard for diagnosing rejection is a pancreas graft biopsy, and treatment includes high dose corticosteroids and or without anti-lymphocyte immunotherapy.

Infection
The infection rate and pathogen type are highly specific based on the type of mechanisms used to drain exocrine secretions from the pancreas. Urinary tract infections are common in bladder drained transplants, although sterile cystitis may occur as well. In small bowel drained pancreas transplants, intra-abdominal infections with aerobic and anaerobic infections cause significant morbidity. CT imaging is used to diagnose leaks, abscesses, and fistulas that may be causing infection.

Other Considerations
Trauma
The management of organ transplant trauma patients is generally no different than that of other trauma patients. One study of 50 solid organ transplant patients presenting to a single institution with trauma found that outcomes were no worse than the general trauma population, but trauma may precipitate episodes of rejection. Other small studies have found a higher incidence of fractures but no increased rate of infection compared to general trauma population.

There are a few specific instances where trauma care does differ for transplant patients. When possible, leukoreduced and CMV negative blood is preferred for patients on full immunosuppression. Heart transplant patients may have clinical tamponade from scarring and adhesions, even in the absence of a pericardium. Pleural adhesions may complicate chest tube placement in a lung transplant patient. Traumatic injury of the transplanted kidney and pancreas are rare, despite its location in the anterior pelvis.

Psychological Aspects
Transplant programs widely use psychosocial selection criteria. In general, the cardiac programs have the most stringent criteria. The side effects of lifelong immune suppression or steroid withdrawal can include anxiety, depression, and insomnia. On the other hand, successful transplantation often improves psychological well-being. Transplant social workers can provide awareness of and access to the social network that should surround each transplant.
recipient. Long-term compliance with all aspects of treatment will minimize graft rejection.

DISPOSITION

Patients with solid organ transplants presenting to the ED have a much higher than average rate of hospitalization, with infection being the most common cause. The insidious nature of the diseases affecting this immunosuppressed population necessitates a thorough structured approach to evaluation. If organ rejection, infection, or drug toxicity is suspected, local transplantation specialists should be consulted. Physicians without significant transplant experience should contact the patient’s transplant center to obtain consultation and to coordinate follow-up care. Patients who are discharged require careful instructions, medication reconciliation to avoid toxicities, and close follow-up.

**KEY CONCEPTS**

- The possibility of organ rejection, infection, or drug toxicity should be considered in all organ transplant patients who present to the ED, because the presentations can be subtle.
- Anatomic issues related to solid organ transplantation are specific to the organ transplanted and time since transplantation but generally involve thrombosis, stricture, or breakdown and leak of the anastomoses.
- Timing since surgery, state of immunosuppression, exposures and risk factors, and graft function should be taken into account at each ED evaluation.
- Differentiation of infection and rejection is often difficult in the ED. Determination is often made only after biopsy of the transplanted organ or positive culture results are identified.
- Infections that occur 1 to 6 months after transplantation are generally immunomodulating viral infections, such as with CMV, or opportunistic infections.
- A patient’s inability to take oral immunosuppressants for even a single day should be considered an emergency condition.
- When prescribing new drugs, care should be taken to avoid drug interactions and toxicity of immunosuppressants.

CHAPTER 188: QUESTIONS & ANSWERS

188.1. A 42-year-old man presents with fever, cough, and shortness of breath. He reports a history of renal transplant approximately 2 months ago. He denies surgical site pain or changes in urine output. Chest radiograph reveals a diffuse interstitial pattern. Although concerned that his fever could be caused by acute organ rejection, you are also concerned about pneumonia. What is the most likely cause of his pneumonia?

A. Cytomegalovirus (CMV)
B. Herpes simplex
C. Klebsiella pneumoniae
D. Listeria monocytogenes
E. Staphylococcus aureus

Answer: A. CMV is the most prevalent cause of pneumonia in the solid organ transplant patient. Infection typically occurs 1 to 6 months after transplant. Infections are serious and often fatal, but aggressive supportive care, as well as treatment with ganciclovir and CMV-specific immunoglobulin, improves outcome. Pneumocystis jiroveci pneumonia is also common and can be indistinguishable from CMV except by bronchoscopy. All infections are more common in immunocompromised individuals, with herpes and Listeria particularly more common in solid organ transplant patients. Klebsiella is typically seen in alcoholics, but it can occur in any patient population. Staphylococcus pneumonia is typically severe and can cause abscess formation or empyema.

188.2. Cyclosporine and tacrolimus are both commonly used immunosuppressant medications in solid organ transplant recipients. Unfortunately, both of them can cause significant side effects. Which organ is most at risk of toxicity from these medications?

A. Brain
B. Heart
C. Kidney
D. Liver
E. Lung

Answer: C. Both exhibit dose-related nephrotoxicity. Tacrolimus has an improved side effect profile over cyclosporine, but it can still cause significant adverse effects. Both exhibit significant drug interactions, and care should be taken when adding or subtracting medications because drug levels can be altered easily, resulting in either toxic or subtherapeutic levels.
The Combative and Difficult Patient

THE COMBATIVE PATIENT

Principles

Combative patients are among the most difficult patients emergency clinicians encounter. Often brought in against their will, they can be agitated, confrontational, nearly impossible to examine, and they may physically harm themselves or others. The emergency clinician should seek to control the patient and the situation, diagnose and treat reversible causes of violence, and protect the patient and staff from harm.

The emergency department (ED) is a volatile environment because of high stress, illness, prolonged waiting times, and frequent lack of communication. The 24-hour open door policy, availability of potential hostages, and widespread accessibility of drugs and weapons compound the potential for violent behavior. The assault-injury rate of health care support occupations is nearly 10 times that of the general sector, and over half of all health care providers will be victims of forms of violence during their careers.1

Emergency care providers throughout the world are more likely than other health care providers to experience violent events, such as verbal threats, physical assaults, and confrontations outside the workplace.1-6 A 2011 survey of 263 emergency clinicians found that 78% reported at least one workplace act of violence within the past year, with 21% reporting more than one episode.4 A 9-month prospective 2013 study of ED health care workers reported an average of over four violent events per health care worker during the study period.1 From a growing body of literature, similar rates of violence and aggression toward physician and nursing staff are typically observed, and both men and women generally appear to be at comparable risk.1,4 Violent cian and nursing staff are typically observed, and both men and literature, similar rates of violence and aggression toward physi -

Incidents are far more likely to be verbal threats and acts of intimidation than physical assaults and, in the ED, may be acted out by patients, as well as their family and other visitors.1-6 The actions of combative patients have consequences that extend beyond the physical injury of ED caregivers, such as provider post-traumatic stress disorder symptoms and lost provider work productivity.1,6,7

Presentation

Patient Characteristics

The pathogenesis of violent behavior is conjectural. Potential causes include environmental, historical, interpersonal, biochemical, genetic, hormonal, neurotransmitter, and substance abuse disorders.6-12 Psychiatric illness is also a risk factor, with schizophrenia, personality disorders, mania, and psychotic depression most frequently associated with violence.6-12 Delusional schizophrenic patients become violent, believing that others are attempting to harm them. They may also have auditory hallucinations commanding harm to others. The patient with acute mania is unpredictably dangerous because of emotional lability, a situation in which pleasantness can quickly turn to aggression. Substance abuse disorders and drug-seeking behavior are consistently associated with violent behavior in both psychiatric and nonpsychiatric populations.12-14 Biologically, the serotonin system largely controls aggression and inhibition, with diminished sero- tonic function possibly disinhibiting aggression against self and others.12-14 Generalized brain dysfunction may predispose patients to violence by disruption of the regulation of aggression, particularly in the prefrontal and temporal cortex.16-18 Cerebral imaging documents both functional and structural impairments in violent criminals and antisocial patients.19-24

Violent behavior also occurs in association with head trauma, hypoxia, hypoglycemia, electrolyte imbalance, infections (particularly herpes encephalitis), drug intoxication or withdrawal or adverse reaction, and metabolic and endocrine derangements. Uncommon organic causes include seizures (eg, temporal lobe), tumors (particularly those in the limbic system), limbic encephalitis, multiple sclerosis, porphyria, Wilson's disease, Huntington's disease, sleep disorders, hyperparathyroidism, and vitamin and mineral deficiencies (eg, folate, vitamin B12, niacin B3, and pyridoxine vitamin B6). Although drug or ethanol intoxication and withdrawal are the most common diagnoses in combative ED patients, the mnemonic FIND ME (functional [ie, psychiatric], infectious, neurologic, drugs, metabolic, endocrine) helps organize consideration of the many important causes of violence (Box 189.1).

Identification of potentially violent patients is more difficult; male gender, prior history of violence, and drug or ethanol abuse have historically been positive predictors, whereas ethnicity, diagnosis, age, marital status, and education have been unreliable identifiers. Overall, the most accurate tools for predicting acute violent behavior likely relies largely on current observed concerning behaviors and clinical observations of patients in the context of past patterns of violence when known or previously documented.25-27

Emergency Department Influences

An annual ED census over 50,000 patients, an average waiting time over 2 hours, and ED crowding are associated with an increased incidence of violence.2,28 The risk of workplace assault in the ED, however, exists across hospitals of all sizes and reflects the rate of violence in the community. Despite these risks, health care providers are typically not trained in the identification and management of combative patients.1,6

Patients armed with lethal weapons pose a serious threat to staff and the potential risk posed by concealed weapons exists in all settings including pediatric EDs. The carriage of weapons in the ED population has previously been estimated at approximately 4% to 8% and up to 27% of major trauma patients; however, only a minority of EDs screen for weapons or use metal detectors.4 Unfortunately, prediction of weapons carriage in any particular
BOX 189.1
Selected Problems Associated With Violence

**PSYCHIATRIC**
- Schizophrenia
- Paranoid ideation
- Catatonic excitement
- Mania
- Personality disorders
  - Borderline
  - Antisocial
  - Delusional depression
  - Post-traumatic stress disorder
  - Decompensating obsessive-compulsive disorders

**SITUATIONAL FRUSTRATION**
- Mutual hostility
- Miscommunication
- Fear of dependence or rejection
- Fear of illness
- Guilt about disease process

**ANTISOCIAL BEHAVIOR**
- Violence with no associated medical or psychiatric explanation (these patients may be managed by the police or security)

**ORGANIC**
- Diseases
  - Delirium
  - Dementia

- Trauma
- Central nervous system infection
- Seizure
- Neoplasm
- Cerebrovascular accident
- Vascular malformation
- Hypoglycemia
- Hypoxia
- Acquired immunodeficiency syndrome (AIDS)
- Electrolyte abnormality
- Hypothermia or hyperthermia
- Anemia
- Vitamin deficiency
- Endocrine disorder

**Drugs**
- Unanticipated reaction to prescribed medication (especially sedatives in brain-injured or elderly patients)
- Alcohol (intoxication and withdrawal)
- Amphetamines
- Cocaine
- Sedative-hypnotics (intoxication or withdrawal)
- Phencyclidine (PCP)
- Lysergic acid diethylamide (LSD)
- Anticholinergics
- Aromatic hydrocarbons (eg, glue, paint, gasoline)
- Steroids

The deleterious effects of violence in the ED can be minimized by employing certain preventive measures and by training staff in techniques to de-escalate and limit violent behavior when it occurs (Box 189.2).

**Initial Patient Evaluation**

Evaluation of the combative patient begins with attention to safety measures. All patients should be screened for weapons before the interview. The use of metal detection is ideal before ED entry, and additional attention may be needed for patients brought to the ED by ambulance and thereby bypassing routine security booths and metal detectors. The practice of undressing patients and placing them in a gown is useful as a non-confrontational search for weapons that discourages fleeing and aids in identification if the patient escapes from the ED.

The ideal setting for the patient interview emphasizes privacy without isolation. The ideal setting is a seclusion room specifically designed for the interview of potentially dangerous patients. Prior to the medical interview, security should be stationed nearby and the door left open to facilitate both intervention and escape for the provider. The patient and interviewer may be seated roughly equidistant from the door, or the interviewer may sit between the patient and the door. Blocking of the door, however, poses a risk of harm to the clinician if the patient feels the urge to escape. Ideally, examination room doors should swing out, and more than one exit should be available. The clinician should have unrestricted access to the door and never sit behind a desk. The room should not contain heavy or potentially dangerous objects that may be thrown. There ideally should be a mechanism to alert others of danger, such as a panic button or a code word or phrase that summons security (eg, “I need ‘Dr. Armstrong’ in here.”). For personal protection of the provider, earrings, necklaces, and neckties should be removed. Personal accessories that may be used against the caregiver, such as a stethoscope or scissors, should also be removed. The physician should be aware of any objects within the room or on the patient’s body that might be used as weapons, such as pens, watches, necklaces, key chains, cell phones, or belts.

Violence risk assessment of a potentially combative patient can be difficult. Violence often erupts after a period of mounting tension. The astute practitioner may identify verbal and nonverbal cues and subsequently have the opportunity to defuse the situation. In a typical scenario, the patient first becomes angry, then resists authority, and finally becomes confrontational and violent. When physicians have a “gut feeling” that a dangerous situation may be developing, they should take appropriate precautions. Violent behavior may also erupt without warning, especially in patients with an organic brain syndrome, so clinicians should not feel overly confident in their ability to sense impending danger. An obviously angry ED patient should be considered potentially violent. Patients with a history of violent behavior are more likely to inflict serious injury, and certain patient behaviors may suggest impending violence (Box 189.3).²⁶,²⁷

To prevent escalation, the patient should be removed from contact with other agitated accomplices, as well as from other provocative patients. A quiet area enabling direct observation is optimal. As increased waiting times correlate positively with violent behavior, consider evaluating the potentially violent patient expeditiously to prevent escalation of aggression. When feasible, moving these patients up in line when triaging care may avoid the challenging consequences of violence for the patient at hand, the ED staff, and the care of other ED patients in the triage area and waiting room. Often, the perception of preferential treatment alone may aid to defuse the patient’s anger.
Emergency Department Preparedness and Prevention of Violence

**GENERAL EMERGENCY DEPARTMENT PREPAREDNESS CONSIDERATIONS**

- Physical and system factors to minimize ED violence risk:
  1. Prominently displayed warning signs prohibiting weapons and alerting entering individuals that they may be screened for weapons.
  2. Nondiscriminatory inquiry about weapon carriage and searches of individuals for weapons with clear local policies for staff about searches and contraband disposal.
  3. A tiered alarm system with panic buttons in each room to activate a central buzzer in the department.
  4. ED placement of at least one telephone with a direct line to police or security to request additional personnel if needed.
  5. Control flow into the ED by limiting access to one or two entrances and consider buzzer access systems, bulletproof glass, and metal bar barriers to protect the physical structure.
  6. A secure examination room with shatterproof ceiling lights, solid ceiling, heavy indestructible chairs, well-secured restraint bed, two outward swinging doors that can be locked from the outside, an emergency distress button that can be activated unobtrusively, and consideration of a video monitoring system.

**PRIMARY PREVENTION**

Control factors encouraging the development of frustration and aggression:

1. Minimize long waiting times.
2. Optimize waiting room environment.
3. The presence of visible surveillance cameras.
4. The presence of a trained visible security force reflecting both hospital needs and anticipated violence based on local community prevalence.

**SECONDARY PREVENTION**

Response to pre-violent agitation and aggression:

1. Recognition of risk (pre-violent patients and their companions).
2. Implementation of de-escalation techniques.
3. Minimize treatment delays of pre-violent individuals.
4. Ongoing staff training in violent management techniques to increase caregiver confidence and comfort while decreasing the rate of aggressive incidents.

**TERTIARY PREVENTION**

Limitation of the actual act of violence once it has occurred:

1. Use of physical and chemical restraints.
2. Appropriate security and police intervention.
3. Apply familiar protocols for dealing with the violent individual.

---

**Therapeutics**

**Verbal Management Techniques**

Consideration of verbal de-escalation techniques should be given to agitated or violent patients prior to implementation of physical restraints or chemical sedation. The agitated but cooperative patient may be amenable to verbal de-escalation techniques alone. This verbal interaction provides an opportunity to assess the patient’s mental status and comprehension, as well as perception of the current situation. However, the uncooperative actively violent patient or potentially violent patient may warrant immediate restraint without the risk to the patient and ED staff of verbal techniques. If the patient remains resistant or violent after verbal techniques, or incapable of interacting appropriately, then restraint is necessary.

Successful verbal management techniques include an effort to make the patient as comfortable as possible, being honest and straightforward during the medical interview, adopting a non-confrontational demeanor, and being an attentive and receptive listener without conveying weakness or vulnerability (Box 189.4). The interviewer should respond verbally in a calm and soothing tone of voice. It is also important to stand at least an arm's length away and to avoid prolonged direct eye contact, approaching the patient from behind, or sudden movements. In some cases, an agitated patient may be aware of the impulse control problem and welcome limit setting by the clinician (eg, “I can help you with your problem, but I cannot allow you to continue threatening me, the emergency department staff, or other patients.”). The interviewer should act as an advocate for the patient. Offering a soft chair or something to eat or drink (not a hot liquid, which may be used as a weapon) may help establish trust, and many patients relax from this attention to basic human needs.
A key mistake in interviewing a potentially violent patient is failing to address the issue of violence directly. The patient should be asked relevant questions about suicidal or homicidal ideations or plans, possession of weapons, history of violent behavior, and current use of intoxicants. Acknowledgment of the obvious (eg, “You look angry.”) may help the patient to begin sharing emotions. If the patient becomes more agitated, it may be helpful to speak in a conciliatory manner and to offer supportive statements (such as, “You obviously have a lot of will power and are good at controlling yourself.”) to help defuse the situation. If this is not successful, a respectful offer of medication or restraints to the patient may prevent further escalation.

Counterproductive approaches to the combative patient include arguing, machismo (“mano a mano”), threats, deception, and condescension. These inappropriate strategies fail to build rapport and may challenge patients to “prove themselves.” An open threat to call security personnel also invites aggression. Clinicians should be aware of their own reactions to such patients and avoid transference of anger. The deception of a patient (eg, “I am sure you will be out of here in no time.”) may serve to invite violent consequences once the false promise is uncovered and an unsuspecting nurse or colleague who follows the interviewer may be victimized. Do not deny or downplay threatening behavior, and if verbal techniques are unsuccessful and escalation of violence occurs, the physician should leave the room and summon help.

Physical Restraints

Physical restraints should be considered when verbal techniques prove unsuccessful. The use of restraints can be humane and effective in facilitating diagnosis and treatment of the patient while preventing injury to the patient or medical staff. Generally speaking, the liability one incurs for restraining a patient against his or her will is negligible compared with the potential liability for allowing a patient to lose control and cause physical harm to themselves or others. Restraints should not be applied for convenience or as a punitive response for disruptive behavior and should be removed as soon as possible, usually once adequate chemical sedation is achieved.

Indications for emergency seclusion and restraint include the prevention of imminent harm to the patient, others, or the immediate environment, and as part of an effective ongoing behavior treatment program. These patients can typically be broadly classified into three categories: (1) those with an organic disorder for whom restraints facilitate evaluation, (2) those with functional psychosis for whom verbal techniques are less effective and restraints facilitate administration of neuroleptics, and (3) those with personality disorders prohibiting the usefulness of verbal techniques. Seclusion or restraint may be contraindicated because of the patient’s clinical or medical condition. Seclusion should not be used in an unstable patient who requires close monitoring and should be avoided when the patient is suicidal (unless adequate continuous observation can occur), self-abusive or self-mutilating, or has had an intentional ingestion of drugs or poisons. The indications for the use of restraints should be documented. Specific statements (such as, “I restrained Mr. Smith because he told me he was going to beat me up and then took a swing at me.”) are preferable to general statements (such as, “I restrained Mr. Smith because he was violent.”).

The implementation of restraints should be systematic and ideally follow a predetermined ED protocol that is implemented when the examiner leaves the room after verbal techniques are unsuccessful. It may be helpful to consider the application of restraints as a procedure analogous to running an advanced cardiac life support code. Whenever possible, the treating physician should not actively participate in restraint application to preserve the physician-patient relationship. The restraint team ideally consists of at least five people, including a team leader. The leader, whether a physician, nurse, or security officer, is to be the only person giving orders and should be the person with the most experience in implementing restraints. Before entering the room, the leader outlines the restraint protocol and warns of anticipated danger (eg, the presence of objects that may be used as weapons). All team members should remove personal objects that the patient could use against them. If the patient is female, at least one member of the restraint team should ideally be female to potentially mitigate allegations of sexual assault.

The team enters the room in force and displays a professional rather than threatening attitude. Many violent individuals calm down at this point as a large show of force protects their ego (eg, “I would have fought back but there were too many against me.”). The leader speaks to the patient in a calm and organized manner, explaining why restraints are needed and what the course of events will be (eg, “You require a medical and psychiatric examination, as well as treatment.”). The patient is instructed to cooperate and to lie down to have restraints applied. Some patients are relieved at the protection to self and others afforded by restraints when they feel themselves losing control. Even if the patient suddenly appears less dangerous, however, once the decision to restrain is made, continue the process and do not negotiate with the patient at this point.

If physical force becomes necessary, one team member restrains a preassigned extremity by controlling the major joint (knee or elbow). The team leader controls the head. If the patient is armed, two mattresses can be used to charge and immobilize or sandwich the patient. Restraints are applied securely to each extremity and tied to the solid frame of the bed (not side rails, as later repositioning of side rails also repositions the patient’s extremity).

Leather is the optimal type of restraint, because it is a physically stronger material and less constricting than typical soft restraints. For this reason, gauze should not be used. Soft restraints may help restrict extremity use in the semi-cooperative patient but are likely to be less effective in the truly violent patient who is continuing to struggle and attempt escape. If chest restraints are used, it is vital that adequate chest expansion for ventilation is ensured. The application of a soft Philadelphia collar to the patient’s neck may minimize head banging and biting. While restraining patients on their sides helps prevent aspiration, we recommend the supine position with the head elevated, because it is more comfortable and allows a more thorough medical examination while providing some protection against aspiration. Once the patient is immobilized, announcing “the crisis is over” will have a calming effect on the restraint team and the patient.

We recommend avoiding the prone restraint position when possible and employing chemical sedation when a patient continues to struggle against physical restraints. Sudden unexpected deaths have been reported in such patients, particularly if left unattended during busy shifts or between multiple sign-outs with various treating physicians. Although healthy volunteers, when restrained and undergoing physical exertion, do not appear to experience clinically significant positional asphyxia, combative ED patients often suffer from other conditions that may predispose to increased morbidity. Patients using cocaine or other stimulants who are restrained in the prone position appear to be uniquely at risk because increased sympathetic tone and altered pain sensation allow exertion beyond normal physiologic limits and sympathetically-induced vasoconstriction may impede clearance of metabolic waste products and induce hyperthermia and rhabdomyolysis. Alteration of respiratory mechanics in an acidemic patient resulting from the position of restraint can be a contributing factor by impairment of respiratory compensation.

After restraints are successfully applied, the patient should be monitored frequently and positions changed to prevent neurovascular sequelae, such as circulatory obstruction, paresthesias, and
rhabdomyolysis associated with continued combative ness. Standardized documentation is recommended for this monitoring to include the specific indication for restraint and, ideally, other colleague agreement that restraints are necessary. Basic patient needs must be met (eg, hydration, toileting needs) and physical restraints should be removed as soon as possible. Review of restraint team performance and critical discussion may reveal opportunities for improvement. Education and rehearsal by staff can improve and maintain restraint skill and improve confidence with this skill.

**Chemical Restraints**

Chemical sedation alone or in conjunction with physical restraint may assist in the safe management of an agitated or violent patient unresponsive to verbal de-escalation techniques. Chemical restraints subdue patients who may otherwise harm themselves or others and facilitate their medical evaluation and treatment. Clinical and administrative guidelines for their use are similar to those for the use of physical restraints. The use of medication to calm a patient may obscure the mental status examination and clinical diagnosis. This should be weighed, however, against the increased risk that both the patient and staff may face if such medication is withheld.

The ideal agent for controlling combative patients should be effective, safe and well tolerated, free of significant side effects and drug interactions, rapid in onset, titratable, and available through multiple routes of administration. Several pharmaceutical agents can quickly achieve safe behavioral control, or “rapid tranquilization,” without oversedation. However, they should be used with caution and close patient monitoring, because there is a paucity of rigorous clinical studies of chemical sedation in unique settings, such as acute delirium, the underlying comorbid or primary conditions of violent ED patients are often unknown, and a degree of individual variation to response to any medication should be anticipated.

Three primary classes of medication commonly used in the ED for chemical sedation are benzodiazepines, first-generation (typical) antipsychotics, and second-generation (atypical) antipsychotics. With these medications, we suggest a patient-based approach to chemical sedative selection based on suspected or known clinical features (Box 189.5).

Benzodiazepines and antipsychotics (also known as neuroleptics) are commonly used either alone or in combination for rapid tranquilization. Chemical restraints should ideally be taken voluntarily by a patient because the offer of voluntary administration may restore some feeling of control and ease escalating agitation. The intramuscular (IM) route is often advantageous in the uncooperative and dangerous patient refusing an oral medication or an intravenous (IV) catheter. As with physical restraints, it is imperative that these patients be evaluated regularly for changes in their clinical status.

**Benzodiazepines.** Benzodiazepines, particularly lorazepam (Ativan) and midazolam (Versed), are often used in the ED for rapid tranquilization of an agitated or violent patient. Benzodiazepines enhance the activity of the major inhibitory neurotransmitter γ-aminobutyric acid to cause anxiolytic, anticonvulsant, and sedative effects. These agents are particularly preferred for the management of agitation caused by ethanol or sedative-hypnotic drug withdrawal, as well as cocaine, amphetamines, and sympathomimetic drug ingestions. Benzodiazepines may be more effective than antipsychotics in reducing delirium and mortality and are useful in patients at risk for seizure or when antipsychotic associated akathisia must be avoided. For these reasons, we prefer the use of benzodiazepines when sedating the patient with agitation from an unknown cause. Although they are generally well tolerated, side effects of benzodiazepines include excessive sedation, ataxia, confusion, nausea, and respiratory depression, which may be amplified in the presence of concurrent alcohol and other depressant use.

Lorazepam is frequently preferred to other benzo diazepines because of its rapid onset of action, short half-life, route of elimination with no active metabolites, and effectiveness by oral, IM, or IV routes of administration. Recommended initial oral, IM, or IV doses of lorazepam range from 0.5 mg to 4 mg. Typical doses for chemical restraint in the ED begin at 1 mg to 2 mg increments IM or IV with upward titration as needed. The onset of action after administration of lorazepam is generally 5 to 20 minutes if

**BOX 189.5**

**Suggestive Patient-Based Approach to Chemical Restraint**

**THE SEVERELY VIOLENT PATIENT**
- Droperidol 2.5 to 5 mg IM/IV, titrate as needed
- Midazolam 2.5 to 5 mg IM/IV, titrate as needed
- Midazolam 2.5 to 5 mg IM/IV with droperidol 2.5 to 5 mg IM/IV, titrate either as needed
- Haloperidol 2.5 to 5 mg IM/IV with lorazepam 2 mg IM/IV, titrate either as needed

**THE UNDIFFERENTIATED SEVERELY AGITATED PATIENT OR WITH STIMULANT INTOXICATION**
- Lorazepam 2 to 4 mg IM/IV
- Midazolam 2.5 to 5 mg IM/IV
- Haloperidol 5 mg IM/IV with lorazepam 2 mg IM/IV

**THE PATIENT INTOXICATED WITH A CENTRAL NERVOUS SYSTEM DEPRESSANT (EG, ALCOHOL)**
- Haloperidol 2.5 to 5 mg IM/IV
- Droperidol 2.5 to 5 mg IM/IV

**THE PATIENT WITH A KNOWN PSYCHOTIC/PSYCHIATRIC DISORDER**
- Haloperidol 2.5 to 5 mg IM/IV
- Droperidol 2.5 to 5 mg IM/IV
- Haloperidol 2.5 to 5 mg IM/IV with lorazepam 2 mg IM/IV
- Ziprasidone 20 mg IM*
- Olanzapine 10 mg IM*

**THE COOPERATIVE BUT AGITATED PATIENT**
- Lorazepam 2 to 4 mg PO
- Olanzapine 5 to 10 mg PO*

**THE ELDERLY PATIENT**
- Reduce above medication dose by half*

*IM, Intramuscular; IV, intravenous; PO, per os (by mouth).

*The safety of atypical antipsychotics in geriatric patients remains somewhat uncertain.
it is given IV or 15 to 30 minutes if it is given IM, with a duration of action of 6 to 8 hours.

Midazolam is also an effective benzodiazepine for achievement of mild sedation and has a more rapid onset of action and a shorter duration of clinical effects than lorazepam. The IM route is used widely to calm the agitated patient with a typical initial dose of 2.5 mg to 5 mg IM. When it is administered IM, the medication usually takes effect in about 15 minutes with a mean duration of 2 hours. In a comparison of midazolam 5 mg IM, lorazepam 2 mg IM and the antipsychotic haloperidol 5 mg IM to sedate violent and agitated patients, all three showed similar efficacy, but midazolam demonstrated a more rapid onset of action and shorter duration of activity than the other medications. The choice of midazolam versus lorazepam may in part be guided by the duration of sedation desired.

Antipsychotics. Antipsychotic medications also play a prominent role in the chemical restraint of the violent ED patient. These medications include the older “typical” (or “classic”) antipsychotics and the newer “atypical” antipsychotics. Although the precise mechanisms of action are unclear, typical antipsychotics appear to strongly block brain dopamine receptors, whereas the atypical antipsychotics less strongly and more specifically antagonize dopamine and serotonin receptors. Both classes of antipsychotics have variable effects on other receptors, such as the adrenergic, cholinergic, and histaminic receptors. The typical antipsychotics can be categorized in terms of their “potency,” a description referring to the relative dosing of the medication and generally predictive of its side effect profile. The incidence of sedation, hypotension, and anticholinergic side effects is higher with the low-potency antipsychotics, whereas the incidence of extrapyramidal symptoms is greatest with the high-potency antipsychotics. Low-potency antipsychotics include chlorpromazine (Thorazine) and thioridazine (Mellaril), medium-potency antipsychotics include loxapine (Loxitane) and molindone (Moban), and high-potency antipsychotics include haloperidol (Haldol) and droperidol (Inapsine).

Of the older typical antipsychotics, the butyrophenones—haloperidol and droperidol—have been widely used in the emergency setting. Haloperidol is the most frequently administered antipsychotic to control the agitated ED patients. It is available in oral, IM and IV preparations, although the commonly used IV route of administration is not approved by the U.S. Food and Drug Administration (FDA). Haloperidol is generally given in 2.5 mg to 10 mg IM doses (often 5 mg IM for the severely agitated awake patient or adult), with half doses administered to elders followed by repeated dosing every 20 to 60 minutes as needed. Effects are usually seen within 30 minutes by the IM route, and the average patient typically requires fewer than three doses for the desired clinical effect.

Droperidol has been commonly used at doses of 2.5 to 10 mg IM and 2.5 to 5 mg IV in a manner similar to haloperidol to control the agitated or combative patient. Compared with haloperidol, droperidol appears to more rapidly reduce agitation at equal IM dosing, has a shorter duration of effect, more sedation, a larger incidence of orthostatic hypotension, and a lesser incidence of extrapyramidal symptoms. When compared with midazolam 10 mg IM, droperidol 10 mg IM appears to have an equally rapid onset of action and requires fewer additional doses for sedation. The clinical use of droperidol decreased markedly after it was given a controversial black box warning in 2001 by the FDA for concern of QTc prolongation and torsades de pointes.

Haloperidol is also associated with QTc prolongation and torsades de pointes. Given the effectiveness and overall safety of these medications and the unclear risk association of potential QTc prolongation, we recommend the cautious use of both haloperidol and droperidol when these medications are administered to patients with other identified risk factors or the known presence of existing QTc prolongation secondary to other antipsychotic agents or methadone. We also recommend obtaining an electrocardiogram or placing the patient on a cardiac monitor before drug administration if possible. If this is precluded by poor cooperation of the violent or agitated patient, we recommend obtaining electrocardiogram as soon as possible once the patient becomes more cooperative.

Common side effects of haloperidol and droperidol are sedation, orthostatic hypotension, and extrapyramidal symptoms. Extrapyramidal symptoms are thought to be due to mesolimbic dopamine receptor blockade. They are not dose related and may occur immediately or days after medication administration. Patients can have akathisia (extreme restlessness) and uncoordinated involuntary movements known as dystonia, including of the muscles of the mouth (buccolingual), neck (torticollis), back (opisthotonos), eyes (oculogyric crisis), and trunk (abdominopelvic). Treatment includes diphenhydramine 25 mg to 50 mg IV or IM or benztpine 1 mg to 2 mg IV or IM acutely and extended for 3 days to minimize symptom recurrence. Both haloperidol and droperidol do have minimal anticholinergic properties and are often coadministered with diphenhydramine or benztropine, so they should not be used to control agitation in a patient with known anticholinergic intoxication. Haloperidol and droperidol should also be avoided in patients with alcohol, benzodiazepine, or other sedative withdrawal syndromes, patients with known seizure disorders, and when possible avoided in pregnant or lactating females and patients with phencyclidine overdoses.

Neuroleptic malignant syndrome is a rare and potentially lethal idiosyncratic reaction estimated to occur in 0.01% to 0.04% of patients receiving antipsychotic medications. Characteristic symptoms include autonomic instability, hyperthermia, “lead-pipe” muscle rigidity, and altered mental status. If neuroleptic malignant syndrome occurs, further antipsychotics should be withheld, and we recommend initiation of supportive treatment and rapid external cooling (see Chapter 155).

Chemical restraint with newer atypical antipsychotics (such as, olanzapine, ziprasidone, and aripiprazole) is generally safe and effective in the treatment of agitated patients, although their role in the treatment of the ED patient is still evolving because most of this research has been done in patients with known psychiatric disorders and not undifferentiated violent behavior. Compared with the typical antipsychotics (such as, haloperidol), these medications appear to provide more tranquillization than sedation, have increased efficacy on both positive and negative symptoms in the outpatient and have fewer extrapyramidal side effects. Their use in the ED is facilitated by IM and oral dissolving tablet formulations that may assist in a smoother transition to oral dosing in those patients requiring ongoing antipsychotic therapy. Although the clinical significance is uncertain, atypical antipsychotics carry a black box warning associating their use with an increased risk of death in elders with dementia-related psychosis and may also cause some degree of QTc prolongation. As a result, we recommend employing the same precautions used with the typical antipsychotics. Because ED experience with these agents is limited, we prefer the use of benzodiazepines and first-generation antipsychotics in cases of severe agitation or violence, pending the completion of more rigorous trials in the undifferentiated ED patient population.

Olanzapine (Zyprexa) is readily available in IM, oral, and oral-dissolving tablet formulations; and it has a reported distinct “calming” effect in clinical practice. It has FDA-approved indications for the treatment of agitation associated with bipolar I mania and schizophrenia. IM olanzapine has an onset of action of 15 to 45 minutes after initial administration and is typically administered as an initial dose of 2.5 mg to 10 mg followed by one or two subsequent doses every 2 to 4 hours for a total
Ziprasidone (Geodon) is FDA approved for treatment of the agitated schizophrenic and bipolar manic patient. Typical dosing is 10 mg IM every 2 hours or 20 mg IM every 4 hours (not to exceed 40 mg/day) with an onset of action of 15 to 30 minutes. Ziprasidone is generally well tolerated, although side effects such as somnolence, dizziness, and headache are common, and it appears to have potentially notable QTc-prolonging effects.

Aripiprazole (Abilify) has FDA-approved indications for the treatment of agitation associated with the schizophrenia or bipolar disorders. Recommended doses for the acutely agitated patient are 5.25 to 15 mg IM (often 9.75 mg) every 2 hours as needed (to a maximum daily dose of 30 mg). Aripiprazole IM (9.75 and 15 mg) may have comparable efficacy to lorazepam 2 mg IM with a low risk of oversedation.

Risperidone (Risperdal) is typically used for schizophrenia and available in an oral and IM depot form with typical dosing of 1 mg to 2 mg. The medication’s time to peak concentration is shorter than some oral second-generation antipsychotics and may be useful when rapid control of agitation is needed and an oral medication is to be given. Orally, risperidone appears to be as effective and tolerable as IM administration of haloperidol. In a randomized trial of 42 agitated patients with psychosis and blinded raters, IM olanzapine, oral disintegrating olanzapine, and oral risperidone solution were found to be as effective as IM haloperidol for the treatment of acute agitation.

Benzodiazepines and typical antipsychotics are commonly used in combination to chemically restrain the agitated or violent patient. Previously demonstrated effective combinations have included midazolam (5 mg IV or IM) with droperidol (5 mg IV or IM) and lorazepam (2 mg IV or IM) with haloperidol (5 mg IV or IM). When given together, lorazepam and haloperidol appear to be more rapidly sedating than either medication alone, have fewer adverse effects, and are compatible within the same syringe for up to 16 hours. Half doses should be administered to otherwise appropriate elders. If additional medication is immediately needed, we recommend consideration of additional midazolam every 3 to 5 minutes or lorazepam every 10 to 20 minutes. Although more investigations are needed to assess the efficacy and safety of the combination therapy of benzodiazepines with second-generation antipsychotics in the treatment of acute agitation in the ED, one multicenter, randomized, double-blind controlled trial found combination of either droperidol (5 mg IV) and midazolam or olanzapine (5 mg IV) and midazolam provided more rapid sedation of acutely agitated ED patients than midazolam (2.5 to 5 mg IV) alone with a mean time to sedation of 14 minutes for the olanzapine group.

**Ketamine.** Ketamine is a dissociative anesthetic with a good safety profile used to manage the violent and acutely agitated patient in the hospital and prehospital setting, including after treatment failure with benzodiazepines and antipsychotics. Although its use in agitated delirium in young adults is increasingly described, we recommend avoiding its use in elders with acute agitated delirium, patients at increased risk for heart disease, and patients with schizophrenia, because it can exacerbate this condition. For the treatment of acute violent agitation in the ED patient, we recommend an initial dose of 1 to 2 mg/kg IV or 4 to 5 mg/kg IM. The onset of drug action is typically 1 to 2 minutes after IV use and often 4 minutes or longer after IM administration, with duration of action of approximately 20 minutes. Notable side effects include hypertension and tachycardia (usually mild and transient), drooling, laryngospasm and other respiratory complications (uncommon), emesis, and emergence reactions.

### Post-Restrain Medical Evaluation

Once combative patients are controlled, they require evaluation for organic causes of their agitated behavior. Separation of functional (psychiatric) from organic (medical) disease is a challenging task complicated by the fact that many patients with psychiatric disorders suffer from organic medical disorders that may worsen their symptoms. Patients who exhibit violent behavior that is caused or exacerbated by an organic problem may rapidly deteriorate if the medical issues are not addressed in a timely fashion. A focused history and physical examination assist the physician in differentiating functional from organic illness.

Historical features may distinguish functional from organic illness (Table 189.1). Patients older than 40 years old who have a new onset of psychiatric symptoms are more likely to have an organic cause. Elders are at higher risk for organic delirium from medical illness or adverse medication reactions. Patients with a history of drug or ethanol abuse may exhibit violent behavior as a manifestation of an intoxication or withdrawal syndrome. The acute onset of agitated behavior, as well as behavior that waxes and wanes over time, suggests an organic origin. Most psychiatric

patients are alert and oriented and have known psychiatric conditions.

The history should include psychiatric, medical, family, and social information, including suicidal ideation, drug and alcohol use, medication use, and any recent changes to prescribed medications. Family and friends can often provide valuable details, because the agitated patient may be unreliable. When they are available, they should be interviewed independently from the patient.

The violent patient should be asked for permission to perform a thorough physical examination to search for an organic cause of violent behavior and to uncover any resulting injury. Restraint of the patient may be necessary to accomplish even the most rudimentary physical examination, including obtaining accurate vital signs. Patients with persistently abnormal vital signs, a clouding of consciousness, or focal neurologic findings are more likely to suffer from organic disease and require further diagnostic evaluation. A careful examination should be mindful of the patient’s general appearance (eg, hygiene, nourishment, tremors), vital signs, evidence of trauma or needle tracks, characteristic odors, neurologic and mental status, and signs of a possible toxic syndrome (Table 189.2).

In general, we recommend tailoring diagnostic studies on the basis of clinical findings.49-52 When safe to do so, an initial rapid blood glucose determination and pulse oximetry should be obtained for all combative patients. Patients younger than 40 years old with a prior psychiatric history, normal physical examination, calm demeanor, normal orientation, and no physical complaints are likely to require no further diagnostic testing.49,52 Additional studies that may be useful in selected patients include serum electrolyte values, blood and urine toxicology screening, serum ethanol level, thyroid function panel, cranial imaging, and electroencephalography. A lumbar puncture may be performed if a central nervous system infection is suggested if the patient is cooperative or properly sedated. Specific medication levels may be determined when toxic levels would affect therapy. An electrocardiogram may be useful in elders and in the setting of a suggested intentional ingestion. Patients who may have intentionally ingested a toxic substance should also have aspirin and acetaminophen level measurements, because these potentially fatal ingestions may be difficult to diagnose clinically.

Although serum ethanol and toxicology screening may not significantly influence a patient’s ED treatment, the psychiatrist may use them to assess the degree to which ethanol or drug use contributes to the patient’s behavioral issues. Ideally, an agreement on a diagnostic strategy should be reached between the psychiatrist and emergency clinician before referral. Unnecessary diagnostic testing prolongs ED length of stay and delays definitive psychiatric care.49

### Disposition and Medical Clearance

The emergency clinician often provides “medical clearance” for the psychiatric or combative patient brought to the ED in police custody or after being placed on a psychiatric hold in the prehospital setting. “Medical clearance” is a misnomer, because a patient is not “cleared” of all possible medical conditions on completion of the ED evaluation; additionally, there is no standard process for the provision of what may be more accurately termed a “focused medical assessment.” A better phrase in this setting is “medically stable for psychiatric evaluation.” Few patients with primary psychiatric complaints are likely to have emergent complications of chronic disease or medical problems contributing to their violent behavior.49,52 However, misattribution of aberrant organic behavior in a patient with known psychiatric disease is a common cause of litigation, and most psychiatrists rely on the emergency clinician’s medical assessment of the patient.

Aspects of medical screening evaluations including specific laboratory tests are often influenced or dictated locally by the policies of the requesting or receiving entities of the patients following ED evaluation. When feasible, we believe that patients with known psychiatric disease who are deemed to be at low risk for active or complicating organic medical conditions can be rapidly referred for psychiatric evaluation once they are calm and cooperative with a therapeutic psychiatric interview. Patients at higher risk for an acute organic illness require further diagnostic studies. Potential high-risk considerations in the prehospital or ED setting include altered mental status, ingestion, hanging, rape, traumatic injury, or unrelated medical complaint.49,52 The medical screening evaluation findings should ideally be communicated to the consulting psychiatrist or other mental health provider and the medical record reflect that the evaluation shows no evidence that an acute medical condition is contributing to the patient’s behavior. When the cause of the patient’s violent behavior is drug or ethanol intoxication, further observation may reasonably be achieved in the ED or another facility where the patient can be safely observed until the effects of the intoxicants have abated and any further warranted mental health examination can occur.

### Assault and Hostage Situations

Interventions to prevent assault and hostage situations, such as optimization of ED security and general preparedness (see Box 189.2), are paramount when considering these violent events, because the rates of extreme hospital and ED violence have increased over time.53,54 Unfortunately, physical assault may occur despite appropriate precautions and interventions. The victim of physical assault or threat of harm with a weapon can take steps to

encounters appear to be associated with physician dissatisfaction and provider. This can be particularly problematic in a cycle of impaired patient-physician interactions, which may dominate the clinical encounter with negative effects on both the patient and physician as the cycle continues. Ultimately, the patient may feel greater in magnitude and result in even further escalation by the physician. The subsequent physician reaction may be even more immediately by offering to administer aid to other hostages. 7. Reassure the hostage taker that a person of authority will arrive promptly to hear their complaints or demands. 8. If a weapon is put down, do not reach for it—it instead attempt verbal resolution of the crisis while awaiting security. 9. Request a hostage negotiator from legal authorities if needed. 3. Maintain a sideward posture, and keep arms ready for self-protection. 4. If choked, tuck in the chin to protect the neck, carotid circulation, and ability to breathe. 5. If bitten, do not pull away—push toward the assailant’s mouth and hold the assailant’s nares shut. If threatened with a weapon:

1. Remember to remain calm, adopt a nonthreatening posture, and avoid sudden movements.
2. Do not reach for the weapon.
3. Comply with demands, and avoid arguing, despair, or whining.
4. Do not bargain, make promises, or lie.
5. Attempt to establish a human connection with the hostage taker.
6. Appear less expendable by offering to administer aid to other hostages.
7. Reassure the hostage taker that a person of authority will arrive promptly to hear their complaints or demands.
8. If a weapon is put down, do not reach for it—instead attempt verbal resolution of the crisis while awaiting security.
9. Request a hostage negotiator from legal authorities if needed.

THE DIFFICULT PATIENT

Principles

The difficult patient is one who is perceived to interfere with the physician’s ability to establish a normal patient-physician relationship. Difficult patients are experienced across medical specialties and may represent 15% to 30% of physician-patient encounters. 56-60 Such patients have been described as invoking feelings such as “heart sink,” dread, anxiety, and dysphoria in their caregivers, causing chaos in the medical setting, and they may carry a number of pejorative labels. 56-60 High frequencies of difficult patient encounters appear to be associated with physician dissatisfaction and burnout. 56-58

The difficult patient-physician relationship is a consequence of aspects of the ED environment, physician characteristics, patient factors, and the complex dynamic interaction of these elements (Box 189.7) 56,61 These elements can act in concert to perpetuate a cycle of impaired patient-physician interactions, which may dominate the clinical encounter with negative effects on both the patient and provider. This can be particularly problematic in

the case of patients with maladaptive patterns of behavior in the presence of unrecognized physician bias or poor communication. Physicians may react negatively to perceived difficult or unreasonable patients, which may summon fear of abandonment in such patients. In response to this perceived threat, the patients may attempt to sustain the patient-physician relationship through escalation of the actions that were originally perceived negatively by the physician. The subsequent physician reaction may be even greater in magnitude and result in even further escalation by the patient as the cycle continues. Ultimately, the patient may feel dissatisfied with care, diagnoses may be missed or made incorrectly due to the dysfunctional interaction, and discharge from the ED may be made prematurely by either the patient or provider. Following such encounters, the physician may experience frustration, exhaustion, a sense of failure or defeat, and fear of litigation. Also, unconstructive patient stereotypes or unrecognized prejudices may develop or perpetuate.

To every patient encounter the ED physician brings personal and professional experiences, bias, personality, and interpersonal skills. Some physicians appear to have a greater number of difficult encounters than other physicians, and similar interactions or
patients may not be perceived as “difficult” by different physicians. Younger physicians, physicians who are more comfortable with diagnostic uncertainty, and physicians with poorer communication skills and psychosocial orientation are all more likely to have difficult patient encounters. Within the complex difficult patient encounter, the physician has the greatest opportunity to positively alter aspects of his or her contribution to interaction. When recognized, strategies exist to help the physician manage negative reactions to difficult patient experiences (Box 189.8). Communication is a critical aspect of the patient encounter affecting medical care, patient satisfaction, and overall patient perception of the experience—some general concepts of communication can aid the difficult patient interaction (Table 189.3).

Specific Disorders

The primary characteristic of a difficult patient is an ability to frustrate or trigger a negative emotional response in the physician. Difficult patients are more likely to be older, widowed or divorced, and have more acute or chronic medical problems. They are more likely to have notable psychiatric, substance or alcohol use disorders, and social issues such as homelessness. Rather than a diagnosis or demographic, it is typically the behaviors of these patients and subsequent therapeutic dynamic that characterize the difficult encounter. Categorizing potentially difficult patients based on four common dominant behavior types—dependent clinger, entitled demander, manipulative help rejecter, and self-destructive denier—allows a structure for the physician to approach and manage challenges that may arise (Table 189.4).

The Dependent Clinger

The “dependent clinger” may have associated personality disorders (dependent, borderline, or histrionic), may be malingering, or possess somatoform disorders or other chronic psychiatric diagnoses. The patient is characterized in part by an excessive need for attention with an initial extreme delivery of gratitude, which the physician may welcome. However, as the amount of care that the patient receives grows, so does their needs and demands. This cycle continues to often leave the physician frustrated and exhausted and eager to discharge or refer the patient to another physician.

When such patients are identified, the physician should carefully establish reasonable expectations and limits before the cycle

<td>Avoid pursuing trivial, chronic, or tangential complaints by redirecting focus</td>
<td>“I think I can help you most right now if we focus on your main concern first.”</td>
</tr>
<tr>
<td>Take a time out</td>
<td>Leaving a patient’s room and returning after both parties have regained composure is prudent if unable to contain one’s frustration</td>
<td>“Thank you for your openness. I need to step out, and I will be back to see what we can do to help you.”</td>
</tr>
</tbody>
</table>

The Entitled Demander

The behavior of these patients can evoke feelings of anger and rejection, and these patients are also at risk for unrecognized depression.56,59 Importantly, these patients are especially likely to seek care in the ED during times of personal crisis. Structuring the encounter to be particularly attentive to the underlying crisis may provide the opportunity to address the underlying problem, rather than the patient’s perceived needs. This scenario is often encountered with patients exhibiting drug-seeking behavior.

The Entitled Demander

The “entitled demander” can include very important persons (VIPs) or other well-informed successful professionals, substance abusers, or personality disorders, such as narcissistic or paranoid. Their behavior is often hostile, intimidating, and threatening, and they may have endless needs and unreasonable demands. These patients fear being helpless in the context of their medical needs, and behaviors that have promoted success in their professional lives become maladaptive behaviors of entitlement to protect themselves from their own insecurity.

The behavior of these patients can evoke feelings of anger and antagonism and a desire to engage in debate and conflict. These power struggles are often counterproductive and only escalate the maladaptive behavior. A physician can address the underlying insecurity and fears by maintaining a supportive relationship.

Limit setting is important to curb escalation of unreasonable demands. Physicians may preserve the patients’ sense of autonomy and control in situations where they otherwise feel helpless by engaging them to participate in the selection of reasonable recommended options of care.

The Manipulative Help Rejecter

The “manipulative help rejecter” is largely characterized by desperate and numerous repeat ED and other medical visits despite expressed certainty that past visits have been failures. Behaviors may appear entitled, manipulative, and self-defeating. These patients may have borderline or antisocial personality disorders and may be malingering. Their complaints are often vague and defy diagnosis, and physicians may feel a sense of futility or failure. The behavior of these patients often stems from a need for physician connection and relationship in the setting of a fear of rejection, and these patients are also at risk for unrecognized depression.56,59

The physician is at risk of both prematurely dismissing the patient’s complaint due to a pattern of frequent visits and medical noncompliance or prematurely beginning an extensive investigation from fear that diagnoses have been missed. Awareness of one’s own cognitive distortions and personal biases can aid in avoiding

inappropriate premature discharge, and seeking collateral information from previous medical records may reveal additional information that can help limit the evaluation and help coordinate ongoing consistent medical care. Although clarifying expectations and limit setting is important, support and empathy can be particularly valuable in these encounters, because expressed lack of concern and dismissal of the patient’s fears may feed an underlying sense of rejection within the patient and fuel the maladaptive behavior.

The Self-Destructive Denier

The “self-destructive denier” may appear hopeless and helpless and in profound denial of their self-destructive and neglectful behaviors. These patients may be violent, chronically suicidal, substance abusers, or have borderline personality disorders. Untreated anxiety or depression may be present. These patients may not personally seek help but instead be referred for care by others. ED care may result in addressing immediate needs (such as, food or shelter), but despite adequate medical intervention, it is likely that the patient’s often very serious problems will persist.

These self-destructive patients can be challenging to treat, because ED staff may feel frustration or even loathe or disgust toward the patient and minimize contact with them. Consequently, the physician and others may unconsciously provide substandard care. By recognizing one’s own feelings and setting realistic expectations of care, the ED care team can avoid poor medical care and may discover patient needs, including mental health conditions or crises or unrecognized social needs.

### KEY CONCEPTS

- The ED should have a written plan of action to deal with violence that integrates the activities of ED staff, hospital administration, security, and local authorities.
- ED staff should be trained to recognize potentially violent individuals and to intervene with verbal de-escalation techniques prior to physical or chemical restraint when possible.
- The emergency clinician should be familiar with the use of physical and chemical restraints and the breadth of options for chemical sedation, as well as situations suggesting use of particular medications. For the undifferentiated severely agitated patient requiring rapid tranquilization, we recommend a benzodiazepine (such as, lorazepam) either alone or with a first-generation antipsychotic (such as, haloperidol).
- The possibility of an organic (medical) cause of aggressive behavior should be considered in all violent patients, even those with known psychiatric disease.
- The negative reactions from difficult patient encounters may result in undesirable implications for both patients and their ED caregivers, including compromised patient care, compassion fatigue, and professional burnout.
- Management of the difficult patient can be optimized by understanding the multiple issues contributing to the impaired physician-patient relationship, including factors of the ED setting (such as, time constraints and lack of privacy), individual physician influences (such as, personal bias and poor communication), and patient contributions to the interaction, including behavioral, social, and substance use issues.
- Pejorative stereotypes of difficult patients should be avoided—to aid in physician strategies for these challenging encounters one should instead aim to characterize the patient’s primary difficult behaviors, such as dependent clinger, entitled demander, manipulative help rejecter, and self-destructive denier.
- Strategies, including understanding one’s own biases and reactions and optimizing communication, are helpful in dealing with the impaired physician-patient relationship.

CHAPTER 189: QUESTIONS & ANSWERS

189.1. Which of the following is a positive predictor of violent behavior in patients?
   A. Age
   B. Ethnicity
   C. Gender
   D. Level of education
   E. Marital status

Answer: C. Identification of potentially violent patients is difficult, with male gender, prior history of violence, and drug or ethanol abuse the only positive predictors. Ethnicity, diagnosis, age, marital status, and education are not reliable identifiers.

189.2. Which of the following medications is associated with the highest incidence of sedation, hypotension, and anticholinergic symptoms?
   A. Droperidol
   B. Haloperidol
   C. Loxapine
   D. Molindone
   E. Thoridazine

Answer: E. Antipsychotics can be divided into low potency (including chlorpromazine and thioridazine), midrange potency (such as, loxapine and molindone), and high potency (such as, haloperidol and droperidol). The incidence of sedation, hypotension, and anticholinergic symptoms is highest in the low potency group, and the incidence of extrapyramidal symptoms is greatest in the high potency group.

189.3. Which of the following antipsychotic medications is associated with the highest incidence of extrapyramidal symptoms?
   A. Chlorpromazine
   B. Haloperidol
   C. Loxapine
   D. Molindone
   E. Thoridazine

Answer: B. Antipsychotics can be divided into low potency (including chlorpromazine and thioridazine), midrange potency (such as, loxapine and molindone), and high potency (such as, haloperidol and droperidol). The incidence of extrapyramidal symptoms is greatest in the high potency group, and the incidence of sedation, hypotension, and anticholinergic symptoms is highest in the low potency group.

189.4. Which of the following disorders is best defined as a pattern of instability of interpersonal relationships, self-image, and affect and marked impulsiveness beginning by early adulthood and present in a variety of contexts? It may be indicated by five or more of the following:
   1. Frantic efforts to avoid real or imagined abandonment
   2. A pattern of unstable and intense interpersonal relationships characterized by alternating extremes of idealization and devaluation
   3. Identity disturbance: Markedly and persistently unstable self-image or sense of self
   4. Impulsiveness in at least two areas that are potentially self-damaging (eg, frequent displays of temper, constant anger, and recurrent physical fights)
   5. Recurrent suicidal behavior, gestures, threats, or self-mutilating behavior
   6. Affective instability caused by a marked reactivity of mood (eg, intense episodic dysphoria, irritability, or anxiety usually lasting a few hours and only rarely more than a few days)
   7. Chronic feelings of emptiness
   8. Inappropriate, intense anger, or difficulty controlling anger (eg, frequent displays of temper, constant anger, and recurrent physical fights)
   9. Transient, stress-related paranoid ideation, or severe dissociative symptoms

Answer: D. Histrionic personality disorder is a pattern of excessive emotionality and attention seeking beginning by early adulthood as indicated by five or more of the following:
   1. Is uncomfortable in situations in which the center of attention is someone else
   2. Interaction with others often characterized by inappropriate sexually seductive or provocative behavior
   3. Displays rapidly shifting and shallow expression of emotions
   4. Consistently uses physical appearance to draw attention to self
   5. Has style of speech that is excessively impressionistic and lacking in detail
   6. Shows self-dramatization, theatricality, and exaggerated expression of emotion
   7. Is suggestible (ie, easily influenced by others or circumstances)
   8. Considers relationships to be more intimate than they actually are
Emergency Medical Services: Overview and Ground Transport

Before the advent of civilian ambulance services, the sick and injured were transported by any means available, including passersby motorists, wagons, farm machinery, delivery carts, buses, and taxicabs. Figure 190.1 depicts the early Larrey ambulance used during the Napoleonic Wars, the Rucker wagon used during the American Civil War, and a modern ambulance used today. In 1865, the Commercial Hospital in Cincinnati established the first hospital-based ambulance service. Four years later, the first city service began at New York's Bellevue Hospital.

In 1965, the President's Commission on Highway Safety recommended the National Accident Response Program to decrease death and injury from highway accidents. Results from a second national survey by the National Academy of Sciences–National Research Council were used to draft a white paper entitled Accidental Death and Disability: The Neglected Disease of Modern Society. Published in 1966, this document described the hazardous conditions of emergency care provision at all levels and outlined the necessary building blocks for future maturation of emergency medical services (EMSs). These national efforts were the impetus for congressional legislation that directed the U.S. Department of Transportation (DOT)–National Highway Traffic Safety Administration (NHTSA) to develop a program for improving emergency medical care.

During the mid-1960s, out-of-hospital cardiac care included field defibrillation programs in Belfast, Northern Ireland, and cardiac arrest research in several United States cities. In 1969, the first National Conference on EMS convened, resulting in the development of a curriculum, certification process, and national registry for the emergency medical technician–ambulance (EMT-A). By 1972, the U.S. Department of Labor recognized the EMT as an occupational specialty. Interested physicians and nurses later provided advanced educational courses and practical experiences for the EMTs and thus began the paramedic providers.

Additional programs prompted Congressional passage of the EMS Systems Act of 1973 (P.L. 93-154), which authorized funding that dramatically improved the development of comprehensive regional EMS delivery systems. Efforts to improve pediatric emergency care occurred in 1984 when Congress adopted the Emergency Medical Services for Children (EMS-C) initiative through the Health Services, Preventive Health Services, and Home Community Based Services Act of 1984 (P.L. 98-555). An Institute of Medicine (IOM) study, released in 1993, promoted the integration of EMS-C not just into existing EMS systems but into comprehensive systems of care provision, including injury prevention, primary and definitive care, and rehabilitation services.

In 1996, the NHTSA published Emergency Medical Services Agenda for the Future, which broadly outlined the principles required for future EMS development. All components of an EMS system, both operational and clinical, were identified and discussed. This document has been used by many individuals and organizations as valuable reference material for planning, administration, and forecasting of the future of EMS delivery. More than 40 years after the 1966 white paper publication, the IOM released a report on the status of emergency care entitled The Future of Emergency Care in United States Health System. The report focused on three separate yet related topics: (1) emergency care: at the breaking point, (2) EMSs at the crossroads, and (3) emergency care for children: growing pains.

A major focus included the need to strengthen the integration of EMS into the entire health care system because lack of such coordination often results in patients being diverted to inappropriate or distant facilities. The recommendation was to ensure that emergency medical and trauma care is organized into a coordinated, regional system such that patients receive care at the most appropriate facility on the basis of their injury or illness. Additional recommendations included national accreditation for paramedic educational programs, adoption of a national certification system for individual state licensure, and adoption of common levels of EMS certification across the United States.

The concern for inadequate funding for EMS systems operations and disaster response was also addressed. In addition to recommending that Congress develop regionally funded, multiyear demonstration projects that provide seamless systems of care, workforce strengthening, evidence-based practices, and disaster preparedness, the IOM recommended that an advisory committee be created to work with the Centers for Medicare and Medicaid Services to improve reimbursement.

Finally, because it is difficult for prehospital providers to maintain the knowledge and skills necessary to care for critically ill or injured children, the IOM report recommended that the care of children be integrated into the overall EMS system, with pediatric emergency care competencies being defined and training enhanced to maintain those competencies. Additionally, a pediatric coordinator should be included in all EMS systems to ensure that equipment, medications, training, and protocols are appropriate for children.

Each of the three IOM reports supported the federal government’s objective to develop national standards for emergency care performance indicators and evaluation and protocols for triage, treatment, and transport of patients. Although debate exists as to whether EMS should remain under the NHTSA, a lead federal agency should be identified. The parent organization should...
examining, certifying, and recertifying providers; record keeping; data collection; and auditing or investigating programs. A description of systems for the 200 most populous cities in the United States is periodically published in the Journal of Emergency Medical Services. For simplicity, the following categorization of systems is used: private and public agencies; basic life support (BLS) and advanced life support (ALS) services; and single-tiered, multi-tiered, and first responder systems.

Private and Public Agencies

Where local government has not assumed primary responsibility for EMS services, communities may depend on private providers. Financial responsibility varies but usually depends on federal reimbursement (Medicare or Medicaid) and user fees. A local government subsidy may or may not supplement the operation. If multiple providers are serving one jurisdiction, calls may be allocated by rotation or specified zone coverage. Dispatching varies by the system but may be by the provider or by a central agency. Medical direction is often provided by a contracted physician or physician oversight board.

Hospital-based EMS systems are few in number and may be managed by a single hospital or hospital corporation. Not all hospital-based EMS programs are considered private, in that the hospital may be a division under local or state government or operate under a public authority. As in private models, financial responsibility is usually paid in the form of user fees, with or without additional subsidies. Dispatching may be provided by a local public safety agency that may also be responsible for police and fire communications. An emergency clinician from a sponsor or base hospital typically provides medical direction for these systems.

A public utility model is a hybrid between private and public design that allows local government to contract with a private or public provider. The successful bidder for service becomes a contracted entity that agrees to provide the specified services (ALS, BLS, or both) to the catchment area and, depending on the arrangement, bill the patient directly or receive uniform reimbursement. Depending on local structure and interagency agreement, dispatching may be performed by an existing public safety organization or by the parent company. Medical direction is usually performed by a specified individual subject to contractual terms.

When government officials were faced with planning and establishment of EMS systems many decided that the fire department was the logical choice to incorporate EMS. Fire stations were strategically located throughout the community, and personnel were already used to providing emergency response. Firefighters could be cross-trained as a firefighter-paramedic or dedicated to either fire or EMS function. Public EMS systems that were not incorporated into fire departments evolved into their own separate entity, referred to as a municipal third-service system. Such agencies are operated by local municipalities and are endorsed and supported by local government. Many cities have been successful in combining police, fire, and EMS under a global public safety agency, with all department heads or chiefs reporting to one manager or administrator. Financially, public EMS systems may be supported by a tax base, which may or may not be supplemented by user fees. Regardless of design, medical oversight for a municipal EMS system may be provided by a physician appointed and contracted by a local government, a local hospital, an advisory council, or a medical oversight board.

Basic Life Support and Advanced Life Support Service

BLS describes the provision of emergency care without the use of advanced therapeutic interventions. Skills include airway

Fig. 190.1. Larrey’s flying ambulance (A), Letterman’s Rucker wagon (B), and the modern ambulance used today (C). (A, Courtesy the National Library of Medicine, History of Medicine Division. B, Courtesy the Library of Congress, Prints and Photographs Division, LC-88171-2585 DLC.)

ensure that research is supported to improve the knowledge base and evidence for the practice of prehospital medical care.

Specific Issues

Emergency Medical Service Systems

Multiple EMS system designs exist, all predicated on the type of community served. Whereas this is a local decision, all states incorporate an administrative office that governs or oversees the provision of EMS activities. The role of the state office of EMS is not to direct any individual service but to assist in planning, licensing services, and establishing or enforcing the scope and standards for practice. Other functions may include training,
management (oral and nasal airways, bag-mask ventilation), cardiopulmonary resuscitation (CPR), hemorrhage control, fracture and spine immobilization, and childbirth assistance. Defibrillation with an automated external defibrillator (AED) is often included by many BLS systems. Services are provided by emergency medical responders (EMRs) or emergency medical technicians (EMTs).

BLS systems may be associated with poor survival rates from out-of-hospital cardiac arrest, especially those not incorporating AED technology. Few urban communities across the United States operate solely at the BLS level. Many rural and some suburban EMS services rely on volunteers who may not wish to become advanced-level providers. Because these services may have low call volumes, it becomes difficult for personnel to maintain advanced skills. Also, such communities may not have access to medical supervision or hospital sponsorship for ALS care.

The effectiveness of ALS, however, for medical and traumatic emergencies is debatable, although systems categorized as ALS offer a more comprehensive level of service by highly educated providers, usually certified at the advanced emergency medical technician (AEMT) or paramedic level. Provider skills include advanced airway interventions, intravenous line placement, medication administration, cardiac monitoring and manual defibrillation, and certain invasive procedures. Most EMS systems in urban cities operate at the ALS level of care.

The number of paramedics in any jurisdiction has come under scrutiny, in that cities with more paramedics per capita tend to have lower survival rates. Although this may seem implausible, one explanation might be that the number of patient encounters per paramedic decreases and skills degrade when that community wish to become advanced-level providers. Because these services may have low call volumes, it becomes difficult for personnel to maintain advanced skills. Also, such communities may not have access to medical supervision or hospital sponsorship for ALS care.

Levels of Provider and Scope of Practice

At the federal level, the NHTSA is responsible for development of the education standards and scope of practice for the different certification levels. The National EMS Education Agenda and the National EMS Scope of Practice Model now define the curriculum, education content, and core competencies for each level of providers. Individual state legislation dictate the provider levels recognized, initial and continuing medical education requirements at each level, testing, and time intervals for course completion and recertification. The following sections outline the new suggested levels of provider and incorporated skills. Suggested hours of training are listed in Table 190.1.

Emergency Medical Responder

The EMR, formerly referred to as first responder, is typically the first to arrive on the scene of an incident. Initial scene and patient assessment along with limited lifesaving interventions is the primary function. Along with CPR and basic airway management skills, the EMR should be able to control hemorrhage and initiate spinal immobilization.

The four elements referred to as the chain of survival by the American Heart Association (AHA), which decrease mortality from out-of-hospital cardiac arrest, are immediate recognition of cardiac arrest and EMS activation, CPR, rapid defibrillation, and ALS. The 2010 resuscitation guidelines of the AHA recommended the addition of a fifth link, post-cardiac arrest care in a regional center. Because early defibrillation may improve the odds of survival of out-of-hospital cardiac arrest, the use of an AED should be a mandatory procedure for the EMR.

Emergency Medical Technician

The EMT, formerly referred to as the EMT-Basic, is the minimum level required to staff a BLS ambulance and is commonly used for nonemergency and convalescent transport services. In addition to the skills of the first responder, the EMT is also involved with triage, more detailed patient assessment, and transportation. Like first responders, EMTs should have the capability of providing early defibrillation.

In 1995, the NHTSA released the revised EMT curriculum to include 46 lessons, each with cognitive, effective, and psychomotor objectives. Many states expanded the course to include more skills, such as AED use, epinephrine autoinjections, albuterol administration by handheld nebulizer or metered-dose inhaler, and use of adjunctive airway devices, such as the extraglottic airway.

Advanced Emergency Medical Technician

The AEMT, formerly referred to as the EMT-Intermediate, was established to allow a more comprehensive approach to care when paramedic services are unavailable or unobtainable. Many states recognize the AEMT certification, but others designate alternative but comparable levels, depending on specific skills and procedures. This level is useful for rural systems, because it provides some ALS care for less cost and educational time expended. The scope of practice for the AEMT varies across the United States. Most systems allow the AEMT to establish an intravenous line, to manually defibrillate, and to administer limited medications.

Paramedic

The most advanced of the prehospital providers, paramedics have the capability to address most prehospital emergencies. Their scope of practice includes a wide variety of therapeutics and...

AED, Automated external defibrillator; CPR, cardiopulmonary resuscitation.

Procedures, including cardiac rhythm recognition, expanded pharmacologic treatments, and advanced airway interventions. Other important invasive procedures include needle decompression of a tension pneumothorax, needle or surgical cricothyrotomy, and transthoracic cardiac pacing.

The initial training course for the paramedic includes didactic, clinical, and field education. All course content focuses on technical and professional competencies. Additional modules are included that allow programs to incorporate an expanded scope of practice. With the expansion of EMS technology and management career options, many paramedic educational programs have advanced from 1-year certificate curriculums to 2-year associate or 4-year baccalaureate degrees. The National EMS Education Standards document recommends that all paramedic education programs be accredited in the future by the Commission on Accreditation of Allied Health Education Programs.

**Future**

To complement many of the educational issues addressed in the EMS Agenda for the Future document and at the request of the National Association of State Emergency Medical Service Officials (NASEMSO), the NHTSA along with the Health Resources and Services Administration under the Department of Health and Human Services published the *Emergency Medical Services Education Agenda for the Future: A Systems Approach*. Setting forth the processes required to improve EMS education delivery similar to what is realized with other allied health care professions, this document aims to increase instructor flexibility and EMS adaptation to community needs and resources, and to standardize levels of certification across the United States. Since publication of this document, the National EMS Core Content, a National EMS Scope of Practice Model of minimum competencies, and the 2009 National EMS Education Standards, which replaces the current National Standard Curricula for each level of provider, have been published. The NASEMSO has been collaborating with multiple EMS stakeholders and the federal partner organizations to assist states in implementing this agenda, including the National Registry of Emergency Medical Technicians, which has revised their examinations. Future goals include the establishment of a national EMS certification program, the requirement for educational programs to be nationally accredited, and the limitation of examinations only to those graduates who completed these accredited programs.

In keeping with the spirit of the EMS Agenda for the Future, which specifically calls for integration of health services and prevention attributes, some systems have implemented programs that engage interprofessional health providers into the existing structures of care. Examples include embedding a nurse triage system at the 9-1-1 access level, where low acuity complaints are determined by vetted algorithms are transferred to alternate call center nurses who determine and arrange appropriate care at a clinic or facility other than an emergency department. Another example that is becoming popular is having prehospital providers, usually at the paramedic level, provide patient evaluation services to pre-identified patients with chronic conditions, such as hypertension, diabetes, congestive heart failure, and substance abuse. These programs, referred to as community paramedics, mobile integrated health, or advanced practice paramedics among others, are designed to prevent or reduce the need for EMS calls and to decrease emergency department utilization for targeted patients or frequent users.

**Material Resources**

Before the mid-1960s, few if any regulations governed system design, operations, and equipment. As EMS development progressed, guidelines for emergency vehicle specifications were
adopted by the DOT and equipment lists were proposed. Today, collaborative efforts from multiple professional organizations continue to publish documents that recommend design, equipment, and medications for ambulances.22

Medications

During the 1980s, many believed that prehospital drug administration was unjustified and simply delayed hospital transport. Moreover, although there was a profound paucity of outcomes-based research into the use of various medications and practices in the prehospital environment, this has improved in recent years.23 There is significant evidence for early defibrillation and certain advanced cardiac life support medications, which are carried by most ALS services. The wide variety of alternative medications is less uniform. This includes respiratory and anaphylaxis medications, preparations for altered mental status, analgesics, and antiemetics. Medications are traditionally administered in the field by the parenteral route, but the intranasal route is becoming popular. The beneficial aspects are that absorption is rapid with an onset of action similar to that of parenteral administration. Medications that are commonly administered intranasally are naloxone for narcotic overdose, midazolam for pediatric sedation, and dimenhydrinate for emesis.

Equipment

Basic ambulance equipment should include items necessary for emergency procedures (ie, airway support, hemorrhage control, fracture and spine immobilization, childbirth), personal protection, patient movement, and basic rescue procedures. Additional patient care equipment is predicated on the level of provision outlined by the system design. Many ALS systems have adopted the equipment necessary for the acquisition of prehospital 12-lead electrocardiograms to provide earlier diagnosis of acute myocardial infarction. This information often guides destination protocols to deliver these patients directly to acute care facilities that incorporate 24-hour cardiac catheterization laboratories with staff to facilitate emergent percutaneous coronary interventions.

Ambulances

Three basic ambulance vehicle designs are recognized by the DOT: type I, type II, and type III. Both type I and type III ambulances incorporate a modular patient compartment mounted on a conventional truck and van chassis, respectively. The type II vehicle is a standard van. The larger medium-duty vehicle, mounted on a business-class chassis, has become popular in recent years. This configuration requires less periodic maintenance and offers extended service time. Each ambulance manufacturer promotes various interior cabinetry and all include sufficient lighting, outlets for 110-volt equipment, suction, oxygen systems, and external audible and visual warning devices. The six-pointed blue star, or Star of Life, surrounding the staff of Aesculapius is recognized worldwide as the standard symbol for EMS.

Communications

Integral to out-of-hospital care systems, EMS communications involve multiple components, all interlinked to support expedient patient care. Effective communication systems include public information and education programs regarding general access to care, technology to ensure simplified access, a means of call prioritization and management of available resources, protocols for providing emergency patient care instructions before EMS arrival, ability to communicate with allied agency and hospital personnel, educational opportunities for telecommunicators, and quality improvement processes.

Access

Since 1973, the 9-1-1 universal emergency access telephone number has been adopted by many communities throughout the United States. Basic 9-1-1 service simply connects a caller to a central communications center or public safety answering point (PSAP). Most primary PSAPs are under the domain of law enforcement. Although many of these handle all public service (police, fire, and EMS) calls, many larger cities have secondary PSAPs for fire and EMS. Enhanced 9-1-1 provides additional information by immediately displaying the caller’s telephone number and address.

Emergency Medical Dispatch

Dispatching encompasses multiple elements that assist patients in receiving expeditious medical care. There are several recognized programs with varying sensitivities and specificities that assist call-takers in identifying a patient’s acuity level on the basis of the caller’s information.

The emergency medical dispatcher (EMD) is responsible for ascertaining the primary medical condition and severity. Communication centers that model their dispatch response protocols by priority use a finite list of common chief complaints, each having associated predetermined questions. Answers to these questions ultimately dictate a predefined response mode. Depending on the response assigned and system configuration, an ambulance (BLS or ALS) and possibly a first responder resource is dispatched to respond in an emergency or nonemergency mode. When critical conditions are identified, the EMD may proceed to give specific pre-arrival instructions to assist the caller in providing critical interventions before EMS arrival. These include procedures, such as opening and clearing an airway, performing CPR, controlling hemorrhage, and assisting with childbirth. Such assistance dramatically narrows the response time interval for receiving emergency medical care.

Systems Status Management and Flexible Deployment

Depending on system size, population served, and resources available, systems status management has proved beneficial. On the basis of historical data, high-performance or peak-demand periods of the day coupled to service areas or call location can be identified so that coverage plans or posting assignments may be instituted. Such mechanisms place ambulances at predetermined locations where potential calls are likely to occur. Response vehicles may be equipped with an automatic vehicle locator that functions as a telemetry unit or a global positioning satellite system that provides a site interface with the computer-aided dispatch system. This site information is helpful in the staging or redeployment of vehicles during periods of high call volume or when resources are limited. To stage and identify closest resources to the callers, technologically advanced agencies are using new programs that incorporate additional factors, such as traffic patterns based on time of day and street configurations.

Field Communications

At the scene or during transport, EMTs usually have the capability of communicating with hospital staff. A consultative patient report may be given to receive medication or intervention orders or simply for arrival notification. Additional information resources may include cardiac telemetry or transmission of a 12-lead electrocardiogram. EMS providers should also have the capability of
communicating with all allied public safety agencies for mutual aid purposes, mass casualty situations, or disaster responses. If air medical services are available, EMS and fire personnel should have the capability of communicating with the helicopter pilot and crew members. In addition to providing a preliminary patient report to the medical crew, scene personnel should relay landing zone information and potential hazards to the pilot.

OVERSIGHT

Federal

Various federal agencies participate in the oversight of EMS development and refinement. Specifically, the lead agency in the federal government is the EMS Division of NHTSA under the DOT. In 2007, the National EMS Advisory Council was formed to provide advice and recommendations from consumers, advocates, and stakeholders regarding EMS to the NHTSA. Additional federal support comes from the EMS for Children Program under the Maternal and Child Health, Department of Health and Human Services. In an effort to better coordinate federal agencies involved with state, local, tribal, or regional EMS, Congress formed the Federal Interagency Committee on EMS in 2005. The purpose of this organization is to simplify the processes and efforts by which federal agencies support EMS by identifying state and local EMS needs and recommending the addition, expansion, or improvement of programs. Although it is not regulatory, the National Association of EMS Physicians is an international organization of physicians and prehospital professionals interested in promoting research, innovation, and excellence in prehospital care delivery.

State

Each state incorporates a governmental agency that oversees EMS. Duties typically include enforcement, regulation, and implementation of EMS rules adopted by the state and possibly a medical board, licensing services, and certifying providers. The NASEMSO assists in developing policy, providing insight, and ensuring leadership and resources for EMS development at the state, regional, and local levels.

Local

Emergency Medical Services Medical Director

An EMS medical director is a physician with specialized interest and knowledge of patient care activities unique to the out-of-hospital environment. Medical oversight must extend from the communications center through all components of field care. Typically, a contractual arrangement for services provides the physician with administrative authority to implement patient care protocols, to interact with all aspects of the system, and to remove a provider from practice if medical care or behavior is substandard. Published guidelines describing the activities and performance of an EMS medical director have been prepared by the National Association of EMS Physicians, and the NASEMSO. On September 23, 2010, the American Board of Medical Specialties approved EMS medicine as the sixth subspecialty available to the American Board of Emergency Medicine (ABEM) diplomates with the first certification examination being administered in October 2013. The Core Content of EMS Medicine is available on the ABEM website.

Medical direction consists of off-line (indirect) and on-line (direct) control. Off-line medical control includes protocol development, personnel education, prospective and retrospective patient care review, and other quality improvement processes. Direct medical control concerns real-time interaction between a physician or designee and the field provider.

Indirect Medical Control

Medical accountability for patient care activities is the basis for indirect medical control and functions either before a patient is encountered (prospective) or after hospital transport has occurred (retrospective). Patient care guidelines and protocol development for EMTs and EMDs, continuing medical education, medical-legal policies, and quality and performance improvement processes are important elements.

Perhaps the most important duty of the medical director is to develop patient care protocols, which are preestablished practice guidelines that define the standard of care for most illnesses or injuries encountered in the out-of-hospital setting. Operational issues, such as hospital designation and destination policies, termination of resuscitation, and patient transport refusal, may be included. Depending on state regulations, protocols may include standing orders for particular clinical situations in which EMTs may perform certain procedures or administer medications for predefined patient conditions before communication with hospital personnel. Protocol development should be driven by published evidence, system resources, and patient needs, and it should include guidelines for triage and care of specific populations of patients, including trauma patients, newborns, and children.

Regardless of local communication protocols, out-of-hospital providers should always be able to discuss a case with a physician for clarification or guidance when clinical questions or controversial situations arise. Furthermore, hospital notification is important when critical patients are being transported.

Medical directors should be familiar with and actively involved in local or regional educational programs for initial and continuing education courses for all levels of EMT certification. Course curriculum development and administration, evaluation, and revision processes should be understood. Systems that incorporate their own educational programs allow modifications that reflect intrinsic needs of the system and the providers.

Field personnel and telecommunicators should be given regularly scheduled courses that improve competency in knowledge and skills. Instructional formats and resources to accomplish educational objectives may include didactic classroom lectures, skill laboratories, direct field observation, and distance learning models for self-paced opportunities. Standardized core content is important for consistency and quality of care.

Once patient care protocols are developed and implemented, there must be mechanisms, such as retrospective patient care report review or direct field observation, for evaluation of individual and system performance and patient outcome. Deviations from specific protocols may reflect problems with individual EMTs, medical control personnel, or the protocol itself, each requiring education and reevaluation. Deficiencies, both operational and clinical, should be identified for appropriate remediation, which may be in the form of counseling, educational instruction, or revisions of system design or patient care protocols. Competency, knowledge retention, and skill performance are measurable parameters. Time standards (eg, out-of-chute time [time from ambulance notification to deployment], response time, and scene time) are equally important measures.

Direct Medical Control

Direct medical control is the concurrent direction of EMTs providing patient care. This may be in the form of radio or telephone communications or by direct scene observation and may be considered centralized or decentralized. In a centralized system, a selected hospital is designated the lead facility (base station
hospital, resource hospital, or sponsor hospital) and is responsible for providing all direct medical control orders and notification regardless of the receiving facility. In a decentralized system, each hospital functions as a base station, providing direction to EMTs transporting patients to its facility.

Personnel responsible for direct medical control must be knowledgeable about the entire EMS system, receiving facilities, protocols, medication formulary and equipment, administrative and operational issues, and medical-legal implications for certain presenting situations. Systems whose protocols include standing orders may require direct communication only for specific reasons. Thus, whereas these medical and administrative protocols may guide EMTs through most circumstances, medical control consultation may assist with medical-legal issues, problems at the scene, patient non-transport, or ethical dilemmas that may be encountered. Furthermore, direct medical control is usually invaluable for notification and staff preparation when critical or potentially critical patients are being transported.

Table 190.2 lists the various levels of EMS oversight, and Table 190.3 lists contacts for agencies and organizations involved in EMS development.

### OUT-OF-HOSPITAL MEDICAL CARE AND CONTROVERSIES IN MANAGEMENT

#### Airway Support and Respiratory Emergencies

**Interventions**

Respiratory complaints account for a significant number of EMS responses. Basic measures to control and support a patient’s airway include manual maneuvers (eg, chin lift or jaw thrust), oral and nasopharyngeal devices, and bag-mask ventilation. At a more advanced level, interventions may include use of supraglottic airway devices (eg, Combitube, laryngeal mask airway, or laryngeal tracheal airway), which have been shown to enable faster and more successful placement than traditional endotracheal tube insertion. Similar studies have demonstrated that paramedics are more successful when using supraglottic airways than endotracheal intubation.

Commonly used by air medical services, drug-assisted intubation (DAI) and rapid sequence intubation (RSI) procedures are well established in ground transport services, despite a lack of supporting evidence. Although many services routinely perform intubation, the effectiveness of out-of-hospital intubation has been challenged, particularly in view of an alarming incidence of esophageal intubation in some systems and poor outcomes with the use of RSI for head-injured patients. Although controversy exists and the debate will continue, most would agree that to have a successful airway management program, the educational and quality management component must be meaningful and should be as comprehensive as possible. For programs using DAI or RSI procedures, the experiential component should include operating room time and/or simulator sessions. Ideally, training would also occur in an ED setting where patients requiring emergent intubation would potentially have the full complement of confounding variables (eg, combative status, full stomachs, blood and vomit in the airway). Such training may be difficult or impossible to achieve, particularly ongoing maintenance of skills, especially in rural communities. Unless EMS systems perform a large number of intubations, with at least several intubations per provider per year, use of an extraglottic device for tracheal intubation should be strongly considered.

Traditionally used in the hospital, prehospital continuous positive airway pressure (CPAP) has been shown to decrease intubation rates and improve patient outcomes. Out-of-hospital use requires strict protocols that outline variables, such as indications and contraindications, clinical applications, mental status assessment, hemodynamic status, and mechanisms for transfer of the patient and devices upon arrival at the hospital.

#### Medications

Most advanced programs have adopted the use of clinically proven medications for bronchospasm, chronic obstructive pulmonary disease, and anaphylaxis, but no studies have demonstrated benefit to administration of these medications in the out-of-hospital environment. Whereas some studies might be considered unethical (eg, an out-of-hospital study of epinephrine for anaphylaxis), others (eg, out-of-hospital use of beta-agonists or steroids for asthma, or loop diuretics for pulmonary edema) could easily be performed. Pending further studies, most systems have adopted the position that these medications do not harm patients in the out-of-hospital setting, may be helpful, and may provide comfort and clinical improvement for most patients experiencing varying degrees of respiratory distress. The overhead for training and maintenance of knowledge related to these medications is rarely considered.
Cardiovascular Emergencies

Interventions

Early research demonstrated the effectiveness of early defibrillation for termination of ventricular fibrillation and improvement of survival rates from sudden cardiac death. Advances in technology have improved such that defibrillators, traditionally used by paramedics, are now used by a variety of public safety responders and bystanders. Public access defibrillation programs are continuing to be implemented throughout the country, with devices being placed in high-volume, populous, and secluded areas, such as airports and airplanes, casinos, churches, office buildings, and other locations identified as high risk for resuscitation. The acquisition and transmission of out-of-hospital 12-lead electrocardiograms is becoming more prevalent as well. Although it is expensive to implement, several studies have revealed minimal delays in scene time while the prehospital electrocardiogram is obtained and a shorter time to intervention (thrombolytic administration or catheterization laboratory admission).

A factor now recognized to improve survival from cardiac arrest is uninterrupted or minimally interrupted chest compressions. Each interruption of compressions (eg, while intubating, checking for pulses, analyzing rhythms) decreases coronary perfusion pressure, which in turn decreases cellular respiration. Additionally, more bystanders may be willing to perform continuous chest compressions if artificial ventilations are discarded.

Although the statistics for cardiac arrest survival across the United States are dismal, those who survive may suffer some degree of hypoxic encephalopathy. Recent evidence supports inducing hypothermia of patients who achieve a spontaneous return of circulation after cardiac arrest, especially with ventricular fibrillation as the initial rhythm, as higher survival rates and level of neurologic functioning are achieved. International guidelines now call for the institution of hypothermia for patients who are resuscitated from cardiac arrest, and many out-of-hospital systems have implemented protocols that may include administration of chilled saline, sedation, or neuromuscular blockers in coordination with receiving hospital EDs.

Medications

Traditional cardiac medications recommended by advanced cardiac life support are used by most ALS systems. A multi-center investigation involving amiodarone as an out-of-hospital agent to terminate refractory ventricular fibrillation and improve survival is ongoing and should provide valid recommendations for future resuscitation guidelines. Whether amiodarone should replace lidocaine for out-of-hospital ventricular fibrillation requires further investigation. The use of out-of-hospital fibrinolytic agents for acute ST elevation myocardial infarction has not gained wide acceptance and may be a useful intervention only for systems having prolonged transport times or if hospitals may not have catheterization or intervention facilities available. Future recommendation for out-of-hospital use of these agents remains speculative.

Traumatic Emergencies

Interventions

Interventions for specific medical emergencies, such as cardiac arrest (ie, defibrillation, intubation, intravenous line, and medication administration), may be effectively performed while on the scene or before hospital transport. Alternatively, it is widely accepted that most interventions for traumatic injuries should be performed en route to the hospital, and all efforts should be extended to reduce on-scene time. Only two interventions should be considered for critical injuries: (1) control of the airway to reverse hypoxemia and to prevent aspiration and (2) stopping of uncontrolled hemorrhage. Although it is a routine part of prehospital trauma care, tracheal intubation is not known to be beneficial for severely injured patients. There are many potential drawbacks to prehospital intubation for major trauma. To be successful, paramedics should rapidly place the endotracheal tube correctly, assess and confirm the placement, and secure the tube to prevent displacement. In addition, providing the correct minute and tidal volumes is equally important. Inadvertent hyperventilation may impair cardiac output and cause further tissue damage. Patients sustaining blunt head injury pose special problems that should be expeditiously addressed and resolved. Intubation is but one means of providing ventilatory assistance and airway protection, but misadventure, complications, and improper post-intubation care may negate these potential benefits. Attempting to intubate head-injured patients may result in dental or soft tissue damage in those patients with clenched teeth, and intracranial pressure may be exacerbated from an intact gag reflex or from subsequent regurgitation. Studies on the use of RSI in head-injured patients reveal that patients experience significant hypoxia and bradycardia during the procedure, and outcome is actually worse. Thus the role of RSI in prehospital airway management in trauma patients is in question, just as it is for medical patients. The use of extraglottic airway devices may be a promising addition to prehospital airway management. Routine use of prehospital intubation is not recommended unless the system can ensure that its providers meet the standards previously outlined.

Emergent hemorrhage control is also essential in reducing mortality in severe trauma. For internal bleeding, limiting of total prehospital time and transfer to definitive surgical care are paramount. Recent evidence on the battlefield has demonstrated the effectiveness of tourniquet application to extremity wounds. These devices may have application in the civilian setting, are quick and easy to apply, and do not result in the complications once thought to exist.

The issue of intravenous fluid administration has gained controversy over the years. Traditionally, high-volume intravenous fluid for hemodynamic instability resulting from traumatic injury was the accepted standard. However, there has been a paradigm shift to restrictive or hypotensive resuscitation for penetrating truncal injuries, because there is evidence that restoration of hemodynamic stability with fluid resuscitation before definitive surgical hemostasis may lead to increased morbidity.

INTERFACILITY AND SPECIALIZED TRANSPORTS

Transportation between health care facilities may occur for several reasons, including patient preference, unavailable diagnostic or therapeutic resource availability at the transferring facility, and managed care requirements that patients be cared for in predesignated hospitals after stabilization. Hospital corporations engaged in networks or alliances that share resources and services depend on interhospital transport systems to convey patients to allied institutions for specialized tests or procedures. Likewise, critical patients admitted to less specialized facilities may need to be transferred to tertiary care or designated trauma centers. Whereas long-distance transports may be best accomplished by air medical services, regional or local transports should use ground systems. These may be provided by either local EMS resources or those owned and operated by the hospital.

Interfacility transfer of patients that is medically indicated must fall under a set of requirements referred to as the Emergency Medical Treatment and Active Labor Act (EMTALA). Although the EMS system providing the transport plays a key role, these guidelines primarily involve particular information and
As with any EMS activity, all interfacility transports should be reviewed for appropriateness of transfer and medical care provided. In 2013, the American College of Emergency Physicians updated the policy statement on EMTALA and patient transfers.

Depending on the patient’s condition, specialized transport services may function at the BLS or ALS level, providing emergency or nonemergency transportation. Patient transfers considered ALS may include interhospital (either ED or intensive care unit) neonatal or high-risk infant, critical cardiac, and trauma transports. Personnel configuration depends on system design and level of care provided. Many programs use a nurse-paramedic combination. Patients requiring specialized care may need the services of specifically trained individuals, such as respiratory therapists, neonatal nurses, or other specialized critical care personnel. The presence of a physician is not mandatory but may be useful in selected cases.

**KEY CONCEPTS**

- Published in 1966, *Accidental Death and Disability: The Neglected Disease of Modern Society* by the National Academy of Sciences–National Research Council was instrumental in EMS maturation in the United States.
- There are multiple system designs for EMS systems, including public and private services, those operating at basic and advanced levels of care, and those that include single or multiple tiers of response capability.
- There are four levels of prehospital providers recognized nationally—emergency medical responder (EMR), emergency medical technician (EMT), advanced emergency medical technician (AEMT), and paramedic, which is the most advanced level.
- The community paramedic provider focusing on population health issues, such as access, chronic disease, and decreasing utilization, and readmission is now being considered by many communities.
- Advances in emergency medical dispatching and positioning resources at locations and during specified times where expected call volumes are prevalent are innovations that are being implemented to decrease response times and improve outcomes.

- Regulatory oversight for EMS systems lies at the individual state level, and medical direction for individual public or private services resides at the local level.
- Direct medical oversight involves real-time interaction with the prehospital providers via face-to-face or by radio communications. Indirect medical direction involves off-line processes such as protocol development, quality improvement, and education.
- Advances in prehospital care of medical patients have included analgesics and anxiolytics that can be administered intranasally negating intravenous routes, noninvasive measures to support patients in respiratory distress, alternative adjuncts in place of endotracheal intubation for managing airways, and tourniquets for controlling hemorrhage.
- More advanced diagnostics (such as, 12-lead electrocardiography and use of stroke screens) have assisted in transporting patients to appropriate facilities based on their illness and acuity.

CHAPTER 190: QUESTIONS & ANSWERS

190.1. Which of the following is not an Emergency Medical Treatment and Active Labor Act (EMTALA) requirement for patient transfer?
A. Acceptance from receiving facility ensured
B. Appropriate patient care data sent
C. Appropriate transportation arranged
D. Complete certification of transfer
E. Medical or surgical stabilization

Answer: E. Box 190.1 provides a list of EMTALA requirements for patient transfer.

190.2. Which of the following is not included in the skill set of an advanced emergency medical technician (AEMT)?
A. Cardiac rhythm recognition
B. Endotracheal intubation
C. Intravenous line placement
D. Laryngeal mask airway
E. Manual defibrillation

Answer: A. Cardiac rhythm recognition is in the authorized skill set of a paramedic. See Table 190.1.
190.3. Which of the following best defines Direct Medical Control in the prehospital setting?
A. Concurrent direction of EMTs providing patient care
B. Development of prehospital care policies
C. Implement quality improvement program
D. Use of prehospital patient care protocols
E. Use of standing field treatment protocols

**Answer:** A. Direct medical control is the concurrent direction of EMTs providing patient care, which can be at the scene or online over radio or cell phone.

190.4. Public access defibrillation programs have been successful in all but which of the following locations?
A. Airports
B. Casinos
C. Churches
D. Office buildings
E. Schools

**Answer:** E. Public access defibrillation programs have been successful in high-volume, populous areas where large numbers of adults gather; schools generally have younger persons who are relatively healthy, so public access defibrillation programs there have not been cost effective.

190.5 Which of the following prehospital interventions has been shown to improve patient outcome?
A. Defibrillation
B. Endotracheal intubation for children
C. Endotracheal intubation for severe head trauma
D. Intraosseous needle placement
E. Needle cricothyrotomy

**Answer:** A. Rapid defibrillation has been shown to improve outcomes for patients in cardiopulmonary arrest; other interventions have not shown proven benefit in the prehospital setting.
CHAPTER 191

Air Medical Transport

Ira J. Blumen | Howard Rodenberg

PRINCIPLES

Background and Importance

Air medical transport (AMT) dates back more than a century to World War I. As early as 1915, the French evacuated soldiers from Serbia using airplanes as ambulances. In 1918, the United States military converted an airplane for the first recorded United States air ambulance to accommodate a litter patient in the rear cockpit. During World War II, more than 1.1 million sick and wounded soldiers were airlifted to the United States during the last 3 years of the war. The Korean War introduced the helicopter to AMT, and more than 20,000 battlefield medical evacuations were flown during the conflict. Utilizing the Bell 47 helicopter, wounded soldiers were strapped to litters outside the aircraft and transported from battalion aid stations to waiting hospital units. During the Vietnam War, Operation Dustoff transported nearly 1 million of the injured from the front lines to care in larger helicopters staffed with medics, to initiate care en route.

AMT had a significant impact on the wounded soldier when considering transport times and mortality. World War I saw battlefield transport times between 12 and 18 hours. Of those surviving transport, mortality was 20%. During World War II, the average time from injury to definitive care was 6 to 12 hours, with a mortality rate of 5.8%. In Korea, the time was 2 to 4 hours, with a 2.4% mortality rate. In Vietnam, no soldier was more than 35 minutes from definitive care, and overall mortality was 2.6%.

Encouraged by the military experience, United States civilian AMT began in 1969 with a hospital-sponsored fixed-wing air medical program. The first civilian helicopter emergency medical services (HEMS) program in the United States was established in 1972. In 2015, the Federal Aviation Administration (FAA) determined that the term HEMS was obsolete, replacing it in official FAA documents with helicopter air ambulance (HAA). Their rationale was that although a critical life and death medical emergency may exist, air ambulance flights are not operated as emergencies.

Aviation Physiology

A working knowledge of aviation physiology is vital to understanding the effects of AMT on pilots, medical personnel, and patients.

Gas Laws

There are four gas laws important to aviation physiology: Boyle’s law, Charles’ law, Dalton’s law, and Henry’s law (Tables 191.1 and 191.2). The cornerstone of aviation physiology begins with Boyle’s law, which describes the effect of gases in an enclosed space. Boyle’s law also is a contributing factor to hypoxia along with Dalton’s law. No one is exempt from the effects of hypoxia at altitude, and the most threatening feature is its insidious onset and the knowledge that the onset and severity of symptoms may vary with individuals.

Additional Stresses of Flight

Other stresses of flight that can affect the patient or crew include temperature fluctuations, dehydration, noise, and vibration. Temperature changes may produce increases in metabolic rate and oxygen consumption.

As altitude increases and the air cools, the amount of moisture in the air decreases significantly. To prevent dehydration during AMT, fluid intake (oral or intravenous) must be monitored carefully, and all patients should receive humidified medical oxygen. Noise and vibration may represent the most ubiquitous stresses encountered in AMT, and both may interfere with patient care or the function of medical equipment. Hearing protection should be worn at all times during aircraft operations by patient and crew. Prolonged exposure to environmental extremes may result in fatigue, motion sickness, disorientation, ear damage, and deterioration in task performance.

SPECIFIC ISSUES IN AIR MEDICAL TRANSPORT

Administrative Structure of Air Transport Systems

Air medical services may take the form of several business models, and it has resulted in tremendous growth of medical helicopters in the United States. In 2015, there were 220 dedicated HEMS HAA programs flying more than 860 dedicated aircraft throughout the nation. From 1990 to 2014, there has been more than a 260% increase in the number of dedicated HEMS aircraft. Over the past 13 years alone, the number has doubled. During that time, what had been the most common HEMS business model in the United States changed. The original and “traditional” non-profit hospital-based operation, sponsored by a single hospital or a consortium of institutions, is now less common than the for-profit community-based programs or hybrid programs. Nearly 70% of the helicopters are for-profit ventures, operated by privately owned or publically traded companies. Public service agencies may also sponsor air medical services or partner with private companies; vehicles used by these programs are often multifunctional aircraft that serve in medical, search and rescue, fire suppression, and law enforcement roles. The Military Assistance to Safety and Traffic (MAST) program operated by the United States Armed Forces provides additional HEMS resources to civilians, but in recent years their role for civilian support has been generally limited to Hawaii and Alaska. Together, the public service and MAST helicopters supply more than 110 additional aircraft for patient transport. There is no accurate accounting of the number of fixed-wing air ambulance companies or airplanes. Although some hospitals sponsor fixed-wing AMT, it is more common for these programs to be private fee-for-service operations.

Types of Missions

Air medical missions may involve primary or secondary response. Primary responses (“scene flights”) are when the aircraft responds directly to the scene of an accident or illness and transports the
The Gas Laws

<table>
<thead>
<tr>
<th>GAS LAW</th>
<th>PRINCIPLE</th>
<th>CLINICAL IMPLICATION</th>
</tr>
</thead>
<tbody>
<tr>
<td>Boyle’s law</td>
<td>The volume of a unit of gas is inversely proportional to its pressure.</td>
<td>Squeeze injuries from contraction of air and associated soft tissues can occur on descent, resulting in barotitis, barosinusitis, and toothache. Reverse squeeze injuries occur on ascent, leading to an increased volume of the air trapped within the space. Examples include the conversion of a simple pneumothorax into a tension pneumothorax and rupture of a hollow viscus. Medical equipment containing closed air spaces, such as IV tubing and pumps, air splints, ventilators, and endotracheal tube and laryngeal airway cuffs, may also be affected by altitude. Responsible in part for hypoxia at altitude due to fewer molecules of oxygen present per volume of inhaled gas.</td>
</tr>
<tr>
<td>Charles’ law</td>
<td>As the volume of a unit of gas rises, the temperature of that volume falls.</td>
<td>Explains why the ambient temperature decreases with increased altitude.</td>
</tr>
<tr>
<td>Dalton’s law</td>
<td>The total barometric pressure at any given altitude equals the sum of the partial pressures of gases in the mixture. Oxygen still constitutes 21% of the atmospheric pressure at altitude.</td>
<td>A decrease in arterial oxygen tension with increasing altitude, resulting in hypoxia. Initial physiologic responses to hypoxia include tachypnea and tachycardia. Initial physiologic responses to hypoxia include tachypnea and tachycardia. With prolonged exposure, cerebral hypoxia causes headache, nausea, drowsiness, fatigue, unconsciousness, and death.</td>
</tr>
<tr>
<td>Henry’s law</td>
<td>The mass of gas absorbed by a liquid is directly proportional to the partial pressure of the gas above the liquid.</td>
<td>Sudden decompression at altitude may result in dysbaric injuries. In scuba diving, rapid ascent can result in gas to come out of solution within the bloodstream, resulting in decompression sickness.</td>

IV, Intravenous.

patient to an appropriate receiving facility. Aircraft involved in secondary responses—interfacility transport—move patients from outlying hospitals to facilities offering higher levels of care. AMT missions may also be classified according to the level of care provided. This may be critical care transport, specialty care transport, or advanced or basic life support.

Air Medical Aircraft

Although ground ambulance remains the primary means of out-of-hospital and interfacility patient transport, AMT has a definite role in the healthcare delivery system. However, no one aircraft is ideal for the needs of all air medical programs or patients.

Helicopters (Rotor-Wing Aircraft)

An estimated 300,000 patients are flown each year by United States HEMS operations. The helicopter offers several advantages over other transport vehicles. Traveling “as the crow flies” at speeds of 120 to 180 mph, helicopter transport time is often 75% less than that for an equivalent distance by ground. The service area of helicopter programs is generally up to 150 to 200 miles from its base of operations, but average transports can be significantly fewer miles. Rotor-wing aircraft have the ability to avoid common traffic delays and ground obstacles and can fly into locations that may be inaccessible to other modes of travel. Helicopter landing zone requirements are a disadvantage compared with ground ambulances but offer an advantage over airport requirements. Air Medical Aircraft landing zone requirements are a disadvantage compared with ground ambulances but offer an advantage over airport requirements.

Disadvantages to HEMS include noise, vibration, thermal variances, and other stressors on patients and crew exaggerated by rotor-wing flight. Weather considerations may at times significantly limit the availability of helicopter transport. In smaller helicopters, cramped spaces and weight limitations may limit the number of patients, transport personnel, or equipment that can be carried. This may sometimes compromise optimal patient care in the transport environment (Fig. 191.1).

Many helicopter programs permit flight only under visual flight rules. When the weather conditions (ceiling and visibility) fall below established program minimums, a flight request may
Air medical crew members represent the broad spectrum of health care providers. AMT services that provide critical care transport, advanced life support, or specialty care transport must staff the vehicle with a minimum of two medical personnel to provide direct patient care. The majority of AMT programs in the United States provide critical care transport teams composed of one registered nurse and an additional crew member (paramedic, second nurse, respiratory therapist, or emergency clinician); most common is the nurse/paramedic crew. AMT crew configuration may also be mission dependent. Some programs will use specialty teams to transport pediatric, neonatal, or high-risk obstetrics patients. Other programs will add a specialty care provider to their “routine” team for these transports. Certain flight conditions and situations may also necessitate consideration of heat, humidity, altitude, distance, fuel on board, and weight of the patient. 

Flight nurses generally have extensive experience in intensive care units (ICUs) or emergency departments (EDs). They may be specialized within the transport team to care for adult, pediatric, or neonatal patients. Paramedics often make their greatest contribution in the transport of critical patients from the scene of illness or injury. Respiratory therapists bring expertise in airway and ventilator management and oxygen delivery systems. Flight physicians may be residents or attending physicians. Much of the early research in AMT crew composition focused on the need for the flight physician. However, only 5% of the United States HEMS programs currently use a resident or attending physician as a dedicated or alternate member of the flight crew.

The AMT environment imposes unique considerations on the air medical flight crew. Human factors work has shown that most medical care procedures are more difficult to perform in an AMT vehicle than in other ground-based settings. Auscultation of the heart and lungs, palpation of pulses, performance of cardiopulmonary resuscitation, endotracheal intubation, radio communications while using a respirator or face mask, and recognition of visual alarms may all be impaired. In addition, fatigue, motion sickness, exposure to engine exhausts, an erratic pattern of work activity, and the high risk involved in AMT operations may affect task performance. Seizures from photic stimuli associated with rotor motion (“flicker illness”) have also been reported. High-fidelity simulation of air medical missions can acquaint flight crew to the novel environment, but fiscal and personnel costs may be prohibitive.

Medical Direction

All air medical services require the active involvement of a physician as medical director, responsible for supervising, evaluating, and ensuring the quality of medical care provided by the AMT team. Emergency clinicians play a significant role, with nearly 70% of all United States air medical directors having a background in emergency medicine, according to a 2007 survey done by the Air Medical Physician Association (AMPA). The medical director must have the final authority over all clinical aspects of the air medical service and should ensure that the flight crew has adequate training and qualifications to optimize patient care. Medical care policies and procedures should be established, including specific provisions for on-line and off-line medical control. AMPA and the National Association of Emergency Medical Service Physicians (NAEMSP) have established guidelines for the medical director of an air medical service.

Safety

Safety is the predominant concern of air medical operations, and ensuring safe flight is a fundamental responsibility of every flight program. Safety must also be an overriding consideration in weighing the risks and benefits of AMT. The role of aircraft pilots and mechanics is essential to the airworthiness of the vehicle, and medical personnel must also be proficient in both routine and emergency operations in and around the aircraft. Checklists will aid in safe practices but alone may not detect significant operational concerns. Crew fatigue and other self-imposed stresses that could affect safety (such as, the use of prescription or over-the-counter medications, tobacco, and alcohol) must be scrupulously avoided.

Weather requirements (“minimums”) must be strictly enforced. On receipt of a flight request, the pilot must verify the weather conditions and the condition of the aircraft. To ensure impartiality, the pilot should not be told of the patient’s condition or acuity. The pilot maintains the unquestioned right to decline a mission because of aircraft or weather considerations. These decisions should not be questioned or influenced in any way by
Landing
because of bad weather or other safety concerns.7,8 The practice
agrees to accept a flight without disclosure to the accepting HEMS
agency or hospital calling numerous HEMS programs until one
the practice of a requesting emergency medical services (EMS)
operator that other programs were called and declined the flight
because of bad weather or other safety concerns.9 The practice
was so common that in 2006, the FAA issued a letter to all state
EMS directors describing helicopter shopping and requesting that
they take action to prohibit this practice.9 Although there may
be circumstances when a subsequent program called can safely
undertake and complete the flight, it is essential that they are
made aware of all of the facts surrounding the request.

The risk of an accident and patient safety is often a concern
when considering HEMS transport for a patient. Cost-benefit
analysis, however, has demonstrated that the risk of crash-related
patient mortality is so low that the impact on calculations of
HEMS use and overall effectiveness is minimal.10 In addition,
available data suggest that after adjustment for patient acuity,
transport by HEMS is associated with lower risk of adverse events
than transport by ground ambulance.11

Landing Zones

Helicopter landing zones are inherently dangerous places. The
most obvious risk of injury is impact with rotor blades. This
danger is heightened during ground operations, because the
blades dip lowest to the ground at the slower rotor speeds associ-
ated with engine start-up and shutdown. Injuries also may occur
as a result of debris being propelled through the air by “rotor
wash,” increased noise levels and an inability to hear warnings,
and slippery surfaces found on exposed landing sites.

Many hospitals have designated landing areas that are appro-
priately lit and secured (Fig. 191.2), with fixed coordinates and
predesignated liftoff and approach patterns. However, most
primary (scene) responses occur at unmarked sites. Ground
personnel must be trained to designate and secure a safe landing
zone and helicopter at all times. Injured victims who
situational reaction. These individuals must be kept clear of the
hospitals and spectators may become hysterical or exhibit signs of an acute

hospitals. (Courtesy Dan Lemkin, MD.)

administrators, flight crew, or other parties. In one witnessed event,
a referring facility repeatedly called an HEMS program insisting
that they come get their patient because their smartphone weather
app showed them that the weather was “good enough to fly.”

The practice of “helicopter shopping” has been a major factor
in a number of fatal HEMS events. Helicopter shopping refers to
the practice of a requesting emergency medical services (EMS)
agency or hospital calling numerous HEMS programs until one
agrees to accept a flight without disclosure to the accepting HEMS
operator that other programs were called and declined the flight
because of bad weather or other safety concerns.7,8 The practice
was so common that in 2006, the FAA issued a letter to all state
EMS directors describing helicopter shopping and requesting that
they take action to prohibit this practice.9 Although there may
be circumstances when a subsequent program called can safely
undertake and complete the flight, it is essential that they are
made aware of all of the facts surrounding the request.

The risk of an accident and patient safety is often a concern
when considering HEMS transport for a patient. Cost-benefit
analysis, however, has demonstrated that the risk of crash-related
patient mortality is so low that the impact on calculations of
HEMS use and overall effectiveness is minimal.10 In addition,
available data suggest that after adjustment for patient acuity,
transport by HEMS is associated with lower risk of adverse events
than transport by ground ambulance.11

Integration of Air Medical Transport Within
Emergency Medical Service Systems

AMT should be an integral resource within a comprehensive EMS
system. Integration begins with the establishment of geographic
service areas. Service areas may be determined on the basis of
program mission description, aircraft range and speed, placement
of specialty centers and receiving facilities, and population densi-
ties. As a general rule, helicopters are generally less useful in urban
settings because of the proximity of health care facilities and a lack
of open and safe landing zones. Paramedics, emergency medical
technicians, and other public safety personnel should be provided
with guidelines specifying when AMT should be considered.

Box 191.1

Landing Zone Safety

Vehicles and personnel should be kept at least 100 ft from the landing
zone.

Spectators should be kept at least 200 ft from the landing zone.

No smoking or running is permitted within 50 ft of the helicopter.

All items (eg, intravenous lines, poles) should be kept below shoulder
height.

The flight crew opens and closes aircraft doors.

The flight crew directs and supervises the loading and unloading of
the patient and equipment.

Ground personnel should use eye and ear protection.

Approach the helicopter only when signaled to do so by the pilot or
an onboard crew member.

Approach and depart the helicopter only forward of the rear cabin
door and in a crouched position with your head down.

Never approach or depart from the rear of the helicopter.

Stay clear of the tail rotor; it is virtually invisible and extremely
dangerous.

If the aircraft is parked on a slope, approach and depart on the
downhill side (greatest clearance under the blades).

Keep the landing zone clear of (or hold on to) all loose articles (eg,
hats, scarves, sheets, pillows).

Protect patient from the dust and debris.

Follow the flight crew’s instructions at all times.

In disaster situations and mass casualty incidents, victims, witnesses,
and spectators may become hysterical or exhibit signs of an acute
situational reaction. These individuals must be kept clear of the
landing zone and helicopter at all times. Injured victims who
exhibit this behavior should not be triaged for helicopter transport,
or they should be transported only with adequate physical or
chemical restraints in use.

If you do not know, ask.

Medicine and Illinois Association of Air and Critical Care Transport (IAACCT), 2015.
These protocols are best developed by EMS medical directors in close collaboration with their air medical colleagues.

**CLINICAL CONCEPTS AND PATIENT CARE**

Although virtually all types of patients have been transported by air medical services, available data do not allow prospective, identification of which patients will benefit from flight. Many questions about the triage of patients to air or ground transport, the efficacy of air medical care, and the precise effects of AMT on morbidity and mortality in medical and surgical conditions remain unanswered. There are many studies indicating which patients can be cared for in the air medical environment, what skills and equipment can be used, and that medical flight is generally associated with safe patient care and a low incidence of adverse effects. Unfortunately, there is a relative paucity of clinical investigation addressing potential solutions to the problems of triage and appropriate use. In an effort to ensure that AMT resources are used wisely, AMPA has established a detailed medical condition list for the appropriate use of AMT. A more general approach to the need for AMT is illustrated in Box 191.3.

In response to the controversy over whether HEMS transport improves patient outcomes, the NAEMSP Air Medical Services Task Force began in 2000 to annotate HEMS outcomes studies published since 1980. This ongoing project has been updated every 3 to 5 years through the Critical Care Transport Collaborative Outcomes Research Effort (CCT CORE). Annotated reviews of HEMS outcomes research from 2014 forward are available on the CCT CORE’s website: www.cctcore.org.

**Trauma**

Most trauma studies have addressed HEMS use for scene response. Methodological heterogeneity precludes formal meta-analysis of the AMT outcomes data. However, existing data consistently show significant improvement in trauma outcomes with AMT. These data support an estimated 20% to 35% improvement in survival rates compared to ground transport, or the saving of three to six lives (fewer for pediatric patients) per 100 air medical trauma flights. As demonstrated by a large 2011 study assessing nearly 75,000 secondary HEMS transports, interfacility air transport of the more seriously injured patient (but not those with lesser severity) is also associated with improved...
outcomes. Two studies also found improved outcomes with seriously injured patients transported by HEMS while also concluding that stable patients may be transported from outlying hospitals to definitive care by ground with equal effect.12 Noting that HEMS represents the only modality by which nearly 28% of United States residents have timely (within 1 hour) access to level I or level II trauma centers emphasizes the vital role of AMT in the care of the injured patient. Studies have also suggested lack of HEMS benefit for the trauma victim, but these studies represent a minority and are limited by confounding factors, such as inclusion of transports to nontrauma centers. Caution should be exercised in definitive statements about the criteria for and the value of AMT, because such statements can be interpreted only in light of the overall local environment in which the transport system exists. HEMS functions best as a part of a comprehensive trauma system and not as an isolated entity.

Work in HEMS casts doubt on the logistical advantages of the helicopter itself. Faster times to trauma centers are not required for better outcomes. It is true that in some studies, subgroup analyses suggest improved trauma outcomes due to HEMS scene response for the more severely injured. However, studies conducted in regions as disparate as California and The Netherlands demonstrate HEMS mortality benefit but find similar scene–to–trauma center times for ground and air transports. For many patients, factors other than speed (such as, the provision of advanced levels of care over that provided by ground personnel) are hypothesized to be responsible for AMT’s benefits.

Studies suggest that most trauma victims transported by air have non–life-threatening injuries. Still, the best large-scale population analysis of more than 40,000 HEMS transports from the 2007 American College of Surgeons National Trauma Data Bank, clearly demonstrated that HEMS–transported patients are indeed of much higher acuity than ground–transported patients.14 The median Injury Severity Score of HEMS patients exceeded the commonly used “severe injury” cutoff of 15; HEMS patients also had a 43% rate of ICU admission.14 More specifically within the trauma population, data from Pennsylvania and California of head injury patients undergoing out–of–hospital intubation demonstrate HEMS–associated improvements in both morbidity and mortality.

AMT is unlikely to improve outcome in those whose injuries are either trivial or grave. Therefore, the decision to request HEMS needs to be based upon the clinical and logistical considerations consistent with recommended guidelines for HEMS dispatch.16 If the Injury Severity Score is collapsed into five ordinal categories, a significant association between helicopter transport and improved mortality is found in the middle three categories (survival odds ratios range from 2.1 to 2.6). Other work has also found that AMT shows benefit over ground transport only for those more seriously injured patients in both rural and urban environments.18 In all these cases, it remains uncertain if improvements in outcome are related to the provision of improved on–scene care or the integration of HEMS into a comprehensive trauma system as opposed to the air transport itself.

Over utilization of HEMS is a significant concern as is over triage to trauma centers. After decades of studies looking at trauma triage, even the best guidelines have trauma center over triage rates as high as 50%.10 The “problems” with trauma triage has a direct impact on the issue of HEMS “overuse.” If it’s not possible to predict with accuracy which patients need to be transported to a trauma center, it is not possible to identify with any greater certainty which patients should be flown. Fortunately, even the acknowledged imprecision of triage to HEMS does not preclude “real–world” identification of AMT–associated trauma outcomes benefit. In a 2010 population–based study in Canada, patients were entered into the study if HEMS services were requested, and outcomes were compared between those who actually underwent AMT and those who went by ground because of the unavailability of HEMS. The study identified a benefit of HEMS, compared with ground transport, of 5.6 more lives saved per 100 transports.19

AMT of injured patients by airplane has also been reviewed in the literature with the focus on longer distance transport. In general, fixed–wing AMT is determined to be beneficial when transporting patients hundreds or even thousands of miles to definitive trauma care.20–23

Cardiac Disorders

Most AMT studies on cardiovascular disease focus on ST–elevation myocardial infarction (STEMI) patients because these represent the largest group of nontrauma air transports. The ability to study HEMS–related outcomes benefit in acute coronary syndrome (ACS) is limited by the lack of validated scores that can be used to stratify risk and predict outcome. Helicopter transport extends the geographic referral base of primary angioplasty centers, and outcomes of patients flown from a distance for definitive care equal outcomes of patients presenting directly to the referral center. AMT systems have been shown to be able to safely transport complicated cardiovascular patients with conditions such as ACS, STEMI, and aortic aneurysm.24

HEMS could conceivably shorten door to percutaneous coronary intervention (PCI) time by transporting patients with STEMI rapidly from hospitals without PCI capability to a referral center. In many circumstances, however, the patient will not have angioplasty of the infarct–related vessel performed within the recommended window and would be best served by receiving thrombolytic therapy at the initial hospital and then being transported in a less emergent fashion. AMT might therefore be better used for transport of critical cardiology patients who require emergent care, such as bypass surgery or balloon pump support that is beyond the capability of the sending hospital. There is also evidence to support HEMS dispatch to rural or wilderness areas for field–diagnosed STEMs.30,31 One study has found HEMS saves at least 30 minutes over ground ambulance transport in nearly 80% of cases. Based on time savings alone then, a conservative estimate suggests that properly used HEMS can save one to two lives per 100 STEMI missions.32

Stroke

Acute stroke patients can be just as time–critical as trauma or ACS cases. With the advent of time–critical therapy for ischemic stroke, HEMS has played an increasing role in the regionalization of acute neurologic care. Early studies demonstrating safety of transport of post–thrombolysis stroke patients have been complemented by case series illustrating the increasing use of helicopter interfacility transport for stroke.

Although it is more common for flight programs to transport patients from smaller hospitals to regional stroke centers, case reports and series have demonstrated the utility of air medical dispatch for primary (scene) transport of patients with strong suspicion of stroke. In both of these scenarios, it has been demonstrated that HEMS can make important contributions when “time is brain.”

Ground EMS can effectively triage and identify patients who would likely benefit from HEMS scene response. Over–utilization is rarely a problem because triage criteria include only the more severe strokes as candidates for HEMS scene response. In one region, ground EMS providers accurately identified stroke, and helicopter–transported patients composed nearly 25% of the stroke center’s thrombolytic volume. The use of strict triage definitions kept inappropriate calls for AMT to acceptably low levels while allowing a significant extension of the geography served by
a stroke center. Performance measurement programs can monitor the efficacy of the AMT service. Considering the improved outcomes that are possible with rapid transport to appropriate specialty care centers, HEMS transport of stroke patients has significant potential.32

High-Risk Obstetric Patients
With appropriate triage, the speed of air transport of the high-risk pregnancy to an obstetric referral center can counter the risk of delivering an infant in an aircraft’s confined space. Case series demonstrate that high-risk obstetric patients transported by air from distant hospitals have outcomes equal to patients presenting directly to an obstetric referral center.34,35 Common reasons for obstetric transport include preterm labor and premature rupture of membranes.

Neonates and Children
The use of AMT to extend the geographic reach of neonatal care centers is reported from many settings. AMT allows infants with medical complications born in remote areas to achieve outcomes equal to those of infants born in urban centers. Although neonates are vulnerable to physiologic deterioration, specialty team air transport is associated with no more derangement in oxygenation and ventilation than transport by ground vehicle. As in the case of trauma, the question remains if the advantage of AMT is related to the use of air transport or specialty services brought to the patient’s side.

Many areas depend on AMT to deliver critically ill or injured children to regional pediatric centers. Although speed of transport may be important, for neonates, the emphasis is often more on the transport team than on the mode of transport. Experienced pediatric transfer teams often bring a level of expertise unavailable to the pediatric patient in the outlying hospital and are noted to have fewer adverse events during transport than non-specialty teams. Appropriate training, experience, and competency are essential. AMT has been shown to be safe for the transport of even the most critical children requiring extracorporeal membrane oxygen support.36

EFFICACY AND COST-EFFECTIVENESS
Cost-benefit is an ongoing issue for AMT. However, when no other option is available, fixed-wing transport is employed, essentially eliminating the question of cost-effectiveness. For HEMS, however, there is much more debate.

The crux of the problem lies in the inability to precisely identify in a prospective manner which patients will truly benefit from fixed-wing or rotor-wing flight, especially when outcome improvements are part of regionalized specialty care systems. As a result, in many cases there is little if any guidance regarding when the medical dispatch is indicated. With use of endorsed guidelines (such as, those endorsed by AMPA) for air medical dispatch, EMS regional authorities should collaborate to generate the best criteria for their own systems, with constant refinement guided by rigorous review. However, in practice, the lack of clear indications and guidelines means that AMT often acts more as a “taxi service” responding to the needs of referring clinicians, hospitals, and EMS services. There is a strong economic argument to be made for maintaining this “looseness” of service, because flight revenues keep AMT services available for those truly in need.

Compared with the cost-benefit ratios of other medical interventions, AMT is well within the accepted range per quality-adjusted life-year saved. One Scandinavian study concluded that the benefits of ambulance missions flown by helicopters exceed the costs by a factor of almost six. Another group from the region estimated that HEMS contributes to the cost-effectiveness of primary PCI, and other investigators have demonstrated the favorable cost-effectiveness of HEMS as part of overall care systems for trauma and stroke patients.32,37-40 HEMS transport of the head-injured patients has been associated with improved outcomes, translating into lower long-term costs for survivors. However, none of these results can be taken as definitive statements, applied universally, because any cost-benefit calculation is applicable only to the system under study.41

Cost-effectiveness determinations are not straightforward. It is difficult to calculate true cost-effectiveness for transports that are not likely to occur (as with high-risk obstetrics cases at risk of precipitous delivery) or that would deliver patients outside critical time windows (as for stroke or cardiac transports) in the absence of AMT. Cost-effectiveness is also difficult to demonstrate when there are no comparison options (such as, transport from coastal islands or locations without road access) or when integrated ground and air transport systems have already become established in ways that effectively prohibit head-to-head comparisons of risks and outcomes (as is true in most of the United States). If we accept that HEMS represents the only mechanism by which more than 80 million American citizens have timely access to mortality-improving high-level trauma center care, it is obvious that some form of air transport is a “must-have” for some EMS regions, and calculations of cost-efficiency fall away in favor of service provision.

Although transport by air is nearly always more expensive than that by ground, the costs of air medical flight should be viewed in contrast with the “real-life” alternative mode of transport. In many cases, and especially where time and distance are significant factors, the total fiscal and opportunity costs of AMT are arguably less expensive than the alternative. Unfortunately, the work of assessing the cost-effectiveness of AMT is complicated by extremely limited information on the cost-effectiveness of ground-based modes of transport. Although the available data do not enable rigorous meta-analysis, most investigations demonstrate that appropriately used HEMS are cost-effective.

FUTURE OF AIR MEDICAL TRANSPORT
AMT faces many challenges. The dramatic increase in the number of medical helicopters in the United States since the late 1990s has heightened concerns for their inappropriate use. AMT works best and provides the most benefit when it is integrated into an overall system of out-of-hospital care and interfacility transport and when systems are in place to educate requesting agencies and professionals about the appropriate use of available air and ground resources.

Currently, the major challenge facing helicopter transport outcomes researchers is to identify triage variables that can prospectively (i.e., at the time of transport vehicle selection) guide use of air medical resources. Advances in ground-based EMS and the availability of critical care ground ambulances for interfacility transports are beginning to offset many of the assumed benefits of AMT. Nonetheless, the regionalization of specialty services, development of new therapies that are highly time-sensitive, and inflexible geography mean that there will always be a role for AMT in emergency care. Thus, the major challenge for the AMT community is to determine not whether but rather in whom there is benefit to air medical flight.

Although appropriate use and outcomes research remain important, the safety of AMT, especially HEMS, must be the highest priority. AMT programs, aviation operators, air medical associations, and regulatory agencies continue to address this issue. However, it is important to recognize the significant role that requesting and receiving personnel can also play with regard to AMT safety.
CHAPTER 191  Air Medical Transport

The references for this chapter can be found online by accessing the accompanying Expert Consult website.

**KEY CONCEPTS**

- Boyle’s law and Dalton’s law have the greatest impact and explain the development of hypoxia and most common altitude-related symptoms. Other stresses of flight that can affect the patient or crew include temperature fluctuations, dehydration, noise, and vibration.

- The helicopter emergency medical service (HEMS) industry continues to grow; however, the business models are changing with the majority of helicopters operated by privately owned or publically traded for-profit companies rather than non-profit hospitals.

- Although most flight programs do both primary (scene flights) and secondary (interfacility) response, ground ambulance remains the primary means of out-of-hospital and interfacility patient transport.

- The helicopter offers several advantages over other transport vehicles, including reducing travel time by up to 75%, ability to avoid common ground delays (traffic, obstacles, and so on), and ability to fly into locations that may be inaccessible to other modes of travel.

- All air medical services require involvement of a medical director responsible for supervising, evaluating, and ensuring the quality of medical care.

- As a general rule, helicopters are less useful in urban settings because of the proximity of health care facilities and a lack of open and safe landing zones.

- Helicopter emergency medical service (HEMS) represents the only modality by which nearly 28% of American residents have timely (within 1 hour) access to level I or level II trauma centers, and the research supports an improvement in trauma survival rates compared to ground transport.

- HEMS may benefit in other time-critical situations, including ST-elevation myocardial infarction (STEMI) patients going to a catheterization laboratory and acute stroke patients going to regional stroke centers.

- Safety is the predominant concern of air medical operations. The practice of a requesting EMS agency or hospital calling numerous HEMS programs after other programs have declined the flight because of bad weather, must be avoided.

- Essential considerations for landing zone safety are as follows: vehicles and personnel should be kept at least 100 ft from the landing zone; spectators should be kept at least 200 ft from the landing zone; helicopters should only be approached when signaled to do so by the pilot or an onboard crew member; never approach or depart from the rear of the helicopter; and if the aircraft is parked on a slope, approach and depart on the downhill side (greatest clearance under the blades).

---

**CHAPTER 191: QUESTIONS & ANSWERS**

**191.1. Which of the following statements is true regarding air medical transport (AMT)?**

A. AMT improves outcomes when used for acute coronary syndrome (ACS) transport.

B. AMT of neonates is associated with more frequent oxygenation/ventilation derangements than ground transport.

C. AMT use after acute stroke is limited by emergency medical services (EMS) provider inaccuracy in stroke patient identification.

D. Faster times to a trauma center are not required for outcomes benefit from AMT.

E. Outcomes after AMT of high-risk obstetric cases are superior to those of patients presenting primarily.

**Answer:** D. Factors other than speed seem to be responsible for AMT benefit. No certain benefit for use during ACS has been demonstrated because most patients would benefit from thrombolysis at the outside hospital followed by advanced capability ground transportation. EMS personnel are able to identify stroke cases with reasonable accuracy. AMT transport of high-risk obstetric cases has outcomes equal to those of patients presenting primarily. Neonates do not suffer greater pulmonary derangements during or after AMT.

**191.2. Which of the following statements is true regarding air medical transport (AMT)?**

A. If the patient’s condition is severe, it is prudent to request service from several AMT providers in the face of marginal weather.

B. Spectators should be kept at least 200 feet away from the landing zone.

C. The pilot should be briefed on the patient’s acuity.
D. The use of a hospital helipad for emergency medical service (EMS) rendezvous triggers the Emergency Medical Treatment and Active Labor Act (EMTALA).

E. Vehicles and personnel should be kept at least 50 feet away from the landing zone.

Answer: B. See Box 191.1 for safety of personnel approaching and disembarking a helicopter. To maintain weather and equipment objectivity, the pilot has no need to know anything about the patient. “Helicopter shopping” between services is strictly discouraged by the Federal Aviation Administration (FAA). The use of a hospital helipad for EMS rendezvous does not trigger EMTALA for that hospital.

191.3. Which of the following statements is correct regarding the aviation physiology gas laws?

A. Boyle’s law explains the physiologic effects of expansion and contraction of gases within the closed spaces of the body that may occur with altitude change.

B. Charles’ law can be shown as $P_t = P_1 + P_2 + P_3 \ldots P_n$.

C. Dalton’s law accounts for the gas changes that result in decompression sickness.

D. Henry’s law explains why the ambient temperature decreases with increased altitude.

Answer: A. Boyle’s law states that the volume of a unit of gas is inversely proportional to the pressure on it. As altitude increases, atmospheric pressure decreases, the molecules of gas grow apart, and the volume of the gas in an enclosed space expands. On descent, there is an increase in atmospheric pressure and gas volumes contract. Dalton’s law states that the total barometric pressure at any given altitude equals the sum of the partial pressures of gases in the mixture ($P_t = P_1 + P_2 + P_3 \ldots P_n$). Charles’ law notes that as the volume of a unit of gas rises, the temperature of that volume falls and explains why the ambient temperature decreases with increased altitude. Henry’s law states that the mass of gas absorbed by a liquid is directly proportional to the partial pressure of the gas above the liquid. Rapid ascent from depth causes the gas to come out of solution within the bloodstream, resulting in decompression sickness.

191.4. Which of the following statements is correct with regard to landing zone safety?

A. During night operations, spotlights should be toward the approaching aircraft.

B. If the aircraft is parked on a slope, approach and depart on the downhill side.

C. In a rear-loading helicopter, it is safe to approach or depart from the rear of the helicopter.

D. It is safe to approach the helicopter when signaled to do so by trained ground personnel.

E. Vehicles and personnel should be kept at least 50 ft from the landing zone.

Answer: B. When the aircraft is parked on a slope, approach and depart on the downhill side where there is the greatest clearance under the blades. Vehicles and personnel should be kept at least 100 ft from the landing zone. Approach the helicopter only when signaled to do so by the pilot or an onboard crew member. Never approach or depart from the rear of any helicopter. Approach and depart the helicopter only forward of the rear cabin door. During night operations, spotlights should be directed at the top of possible hazards, not toward the approaching or departing aircraft.
Disaster Preparedness

Carl H. Schultz | Kristi L. Koenig

PRINCIPLES

Disasters occur in all areas of the world and cause harm to populations, property, infrastructure, economies, and the environment. Harm to populations includes death, injury, disease, malnutrition, and psychological stress. Recent catastrophes include earthquakes in China (2008) and Haiti (2010) (Fig. 192.1); devastating tsunamis in the Indian Ocean (2004) and Japan (2011); severe flooding in Australia (2011); tornadoes in Arkansas, Tennessee, and Kentucky (2008); hurricanes in the United States (2012) and the Philippines (2013), and the Ebola outbreak in West Africa (2014). Increasing population density in floodplains and in earthquake- and hurricane-prone areas and the effects of climate change point to the probability of future catastrophic disasters with large numbers of casualties.

Factors that indicate an increasing probability of mass casualty incidents include terrorist activity; increasing population density in floodplains, seismic zones, and areas susceptible to hurricanes; production and transportation of thousands of toxic and hazardous materials; risks associated with fixed-site nuclear and chemical facilities (illustrated by damage to the Fukushima nuclear power plants after the 2011 Japan earthquake and tsunami); the possibility of catastrophic fires and explosions; and climate change. As an example, the United States Geological Survey has identified volcanoes in the western United States and Alaska that are likely to erupt in the future, including Mt. Hood, Mt. Shasta, and the volcano underlying Mammoth Lakes in California. Because of the rising population density in these areas, hazards from volcanic activity are increasing. Ash from the 2010 Eyjafjallajökull eruption in Iceland grounded aircraft in Europe for weeks.

Given this probability and the increasing role of emergency medicine in disaster mitigation, preparedness, response, and recovery, this chapter discusses disaster planning and operations with emphasis on the role of the emergency clinician. The emergency clinician has extensive responsibilities for community disaster preparedness and disaster medical services, including response to terrorism. In position and policy documents, the American College of Emergency Physicians (ACEP) outlines the scope of emergency medicine’s involvement in preparedness and response to disasters and terrorism, stating that “emergency clinicians should assume a primary role in the medical aspects of disaster planning, management, and patient care.” In addition, ACEP facilitated creation of national disaster and terrorism-related core competencies for emergency department (ED) personnel and emergency medical service (EMS) professionals through a grant from the Robert Wood Johnson Foundation.

A committed ED alone is insufficient to provide hospitals with a successful disaster preparedness program. Institutional commitment by every hospital department and the administration is necessary to coordinate effectively with system-wide resources for disaster management. An integrated comprehensive health care system response is especially critical for providing care when demand exceeds available resources, a concept referred to as hospital surge capacity. A partial listing of sources for general disaster medicine information can be found in Table 192.1.

Surge Capacity

The concept of surge capacity has emerged as a way to manage an event that produces a sudden influx of casualties with medical and health needs that exceed current hospital resources. This can be due to either the volume or types of victims. The three basic components of the surge capacity system are commonly referred to as the three Ss: staff (hospital personnel), stuff (supplies and pharmaceuticals), and structure (physical location and management infrastructure). A complete discussion of surge capacity is beyond the scope of this chapter but has been published elsewhere.

Within the context of surge capacity, new protocols are being developed that address allocation of resources when the medical and health needs of a population exceed current inventory. The issues involve creation of an equitable system for scarce resource allocation strategies, including, but certainly not limited to, the assignment to an intensive care unit. Although no universally accepted approach currently exits, the Institute of Medicine has published a consensus based document that suggests approaches to optimize patient outcomes in a resource-constrained environment.

Definitions

One of the challenges facing those responsible for disaster preparation is that no standard definition of disaster exists. In the most general terms, one might define a disaster as a severe supply and demand mismatch where the need for resources exceeds the supply. This suggests that a disaster is defined more by the resource and need discordance than the actual size of the event. For example, many would consider a plane crash a disaster, yet it may not even approach overwhelming of the resources of the local responders. Because disaster medicine is multidisciplinary and depends on the integration of multiple levels of responders, the use of a common, precise terminology is essential.

In general terms, an event can be considered a disaster when it overwhelms response capabilities. These response capabilities can change in diverse environments or even in the same location at different times of the day or days of the week. A multiple-vehicle collision with 6 critically injured patients and 12 patients with minor injuries could overwhelm both the EMS system and the hospital in a small rural community. In an urban area with multiple hospitals that participate in a trauma system, however, this same event could be managed with routine resources. Thus it is the functional impact on the specific entity that is the key concept in determining whether a disaster exists.

Classic Terminology

The words internal and external refer to a hospital setting to help distinguish whether an event has occurred within the hospital grounds (internal) or in the community (external). This concept distinguishes between preparing for casualties to arrive at the hospital and managing casualties or resources within the hospital.
CHAPTER 192 Disaster Preparedness

Hurricane Katrina in 2005 resulted in a similar number of deaths, but caused such massive destruction, including the loss of medical and health infrastructure, that federal disaster medical assistance teams (DMATs) were deployed to Louisiana to provide medical personnel and supplies.

One proposed model for what is common disaster vernacular eliminates the word disaster and replaces it with potential injury-creating event (PICE). The PICE nomenclature is an attempt to resolve the challenges associated with diverse meanings for disaster. This model is referenced in the Joint Commission standards and in publications from several countries. The PICE system is discussed here to help clarify important concepts in describing an event.

### Potential Injury-Creating Event Nomenclature

The acronym PICE and its modifiers concisely describe the critical features of most types or degrees of disaster. The same occurrence can have different effects at different points in time; thus, as an event evolves over time, its description may change.

Modifiers are chosen from a standardized group of prefixes along with a stage to indicate the need for outside medical assistance (Table 192.2). The first prefix (column A) describes the potential for additional casualties. The second prefix (column B) describes whether local resources are overwhelmed and, if so, whether they should simply be augmented (disruptive) or whether they require total reconstitution (paralytic). The third prefix (column C) shows the extent of geographic involvement. Column C refers strictly to the affected region and not to the location that sends assistance. Rather, the “stage” rating scale defines the likelihood that outside medical assistance will be needed either to augment or to completely reconstitute resources. Stage 0 means that there is little or no chance. Stage I means that there is a small chance and requires placing outside medical help on alert. Stage II means that there is a moderate chance and outside help should be placed on standby. Stage III means local resources are clearly overwhelmed and require the dispatch of outside resources and personnel.

Fig. 192.1. Large-scale catastrophes, such as this earthquake in Haiti (2010), have the potential to cause much injury and psychological stress.

This geographic distinction between internal and external may be useful, but it has severe limitations. Many events can be both internal and external to the facility at the same time (e.g., major earthquake or hurricane). Furthermore, simply identifying the location of the event does not answer the critical question: How are response capabilities affected?

An etiologic descriptor for an event is another customary classification. However, it does not matter whether a disruption in the ability of the hospital to respond is caused by nature or by humankind. The key consideration is what actions are required to mitigate and then to rectify the situation. Although the terms natural and man-made are prevalent disaster descriptors, they generally do not add anything of value, and therefore some experts have advocated removing them from the disaster lexicon, particularly because the etiology of the event may be unclear in its initial aftermath. A biological event initially considered as a natural occurrence may only much later be identified as terrorism.

Some definitions have been based on the number of casualties. As previously described, the absolute number of patients is much less important than whether their medical and health needs exceed the resources to care for them at a given point in time. The attack on the World Trade Center in 2001 (Fig. 192.2) illustrated this point. Although over 2000 victims died in the collapse of the twin towers, the actual impact on the overall health system of New York City was relatively mild. The capacity of the system to care for citizens living in New York remained intact. In contrast,
Emergency Medical Services and Disaster Preparedness

should also be planning for events that, although rare, result in catastrophic consequences. The major peacetime threat to life and limb in the United States is probably a large earthquake in a densely populated area or a terrorist attack, although the threat from flooding is increasing. The disaster planner should prospectively identify all such hazards and prepare contingency plans for each.

### SPECIFIC ISSUES IN DISASTER MANAGEMENT

#### TRIAGE

The term triage derives from the French verb trier, meaning “to sort.” The concept of triage was used as far back as Napoleon’s time to assign priorities to treatment of the injured when resources were limited. Priority is given to the most salvageable patients with the most urgent conditions. Some EDs continue to use triage in the hospital setting, although this daily practice has little in common with triage during disaster conditions. For those EDs that continue to use standard triage, it is intended to identify the most seriously ill patients with time-dependent conditions and to

| Static | Controlled | Local | 0 | None | Inactive |
| Dynamic | Disruptive | Regional | I | Small | Alert |
| Paralytic | National | International | II | Moderate | Standby |

**Hazard Vulnerability Analysis**

An important consideration in disaster planning is an awareness of the types of events for which the hospital or community is vulnerable. The classic example is the monumental risk from earthquakes in the central United States resulting from the combination of the New Madrid fault and the limited seismic safety requirements for buildings in that area. The planner needs to learn what types of support are available from outside agencies (e.g., hazardous materials decontamination from fire departments, and information from poison control centers). Although awareness of such resources is critical, contingency plans should be available when such assistance is not accessible.

After performing a hazard vulnerability analysis (www.calhospitalprepare.org/hazard-vulnerability-analysis), emergency planners should consider the most probable events and prepare for them. Although the approach to preparedness is generic, specific environments require special preparation, and there

Routine Multiple-Casualty Triage

To assist in the understanding of triage techniques, it is useful to consider a routine out-of-hospital event with multiple casualties (e.g., a multivehicle collision). In such situations, rescue personnel often use a simple triage and rapid treatment (START) technique that depends on a quick assessment of respiration, perfusion, and mental status. These three assessments can be remembered by the mnemonic RPM (respirations, perfusion, and mental status).

Initially, all victims who are able to walk are asked to move away from the incident area. These patients are classified as green, or “walking wounded,” and are reassessed after the more immediately critical patients are triaged.

The Pediatric Triage Tape (PTT) and JumpSTART have been proposed for the triage of children. JumpSTART is a modification of the START triage protocol that includes an additional step of five rescue ventilations for children presenting apneic and modification of criteria for hypoventilation and tachypnea, as well as for a decrease in mental status. The PTT uses criteria that change in proportion to increasing victim size. The parameters for a child 50 to 80 cm in length are illustrated in Figure 192.3. When comparing sensitivity and specificity of PTT to JumpSTART in pediatric trauma patients, the PTT demonstrated superior outcomes.

As illustrated in Figure 192.4, a rescuer can assess each patient in seconds, quickly checking respiratory rate, pulse, and ability to ensure that they receive rapid care. The goal of disaster triage is clearly different, that is, “to do the most good for the most people.” In other words, there is a shift from focus on individual patients to focus on the entire affected population. It can be difficult for physicians to realize that to achieve the goal of maximizing benefit to an entire population of patients they may need to let some patients die with comfort care only. Under true disaster conditions, cardiopulmonary resuscitation should not be performed.

Fig. 192.3. Pediatric Triage Tape (PTT) algorithm for a child 50 to 80 cm in length.

Fig. 192.4. Simple triage and rapid treatment (START). Victims who can walk are identified first and triaged into the “minor” category. Those remaining are triaged using the algorithm. (Modified from Triage—START and SAVE. In: Medical disaster response training course syllabus, Dana Point, CA, 1993, Medical Disaster Response.)
follow commands (mental status), and divide the patients into the remaining three categories: red (immediate), yellow (delayed), and black (deceased). The only patient care interventions provided during this process are the opening of an obstructed airway and direct pressure on obvious external hemorrhage. At this point, patients are generally transported to a hospital for definitive care. Most often, patients arrive with a color-coded triage tag and are reassessed and re-triaged by the hospital staff (Fig. 192.5). An outcomes-based evaluation of the performance of START triage in an actual disaster (2002 Placentia Linda train crash) demonstrated acceptable levels of under triage (100% sensitivity of the red category and 90% specificity of the green category). However, significant amounts of over triage occurred. Use of START also appropriately prioritized the transport of victims, with patients triaged as red arriving at hospitals earlier than patients triaged as yellow or green.

A multidisciplinary group proposed a potential national triage system for the United States. The result, derived by consensus of opinions, was referred to as SALT (sort, assess, lifesaving interventions, and treatment or transport). It differs from START mainly in the assessment of respirations (ie, relies on a qualitative evaluation of respiratory distress rather than a number), the requirement for performance of certain emergent interventions (chest decompression), and an unstructured estimate of survivability. The algorithm is more complicated than START, and no current data exist evaluating its sensitivity, specificity, or other performance characteristics after use in an actual incident. As such, it is not currently possible to make recommendations for its use.

### Catastrophic Casualty Management

Triage during a widespread, catastrophic disaster differs from triage performed in routine out-of-hospital and hospital settings. The number of victims is vastly increased, while medical resources are severely limited or even initially absent. Patients may remain on scene for an extended period and should be frequently re-assessed. If hospitals remain accessible, patients tend to seek care at the closest one, a phenomenon known as convergence. Hospitals close to the disaster scene are overwhelmed, whereas hospitals located only a few miles away may receive few if any patients. The triage process will then be decentralized, occurring at multiple sites, or compartments, simultaneously throughout the disaster zone. Rather than a single scene or localized disaster, this can be thought of as a compartmentalized disaster.

To address this situation, researchers developed the Secondary Assessment of Victim Endpoint (SAVE) system of triage. The SAVE triage system is designed to identify patients who are most likely to benefit from care available under austere field conditions in a resource-poor environment. When it is combined with the START protocol, SAVE triage is useful for any scenario in which multiple patients experience a prolonged delay in accessing definitive care.

The SAVE methodology is designed for use by health care providers under two conditions: (1) for those working within the disaster zone that begin caring for patients immediately but may not be able to transport patients to a definitive care facility for days and (2) for those caring for patients within hospitals where demand for resources exceeds supply. This second situation can occur as hospitals attempt to increase surge capacity. It is immediate and dynamic rather than delayed and static. Although there are many elements in common with other triage systems, rapid transport to a functional medical center within the “golden hour” may not be possible.

The SAVE triage methodology divides patients into three categories: (1) those who will die regardless of care, (2) those who will survive without care, and (3) those who will benefit from austere field interventions. Only those patients expected to improve receive care beyond basic or comfort measures. The decision to place patients in a particular group is based on field outcome expectations derived from existing survival and morbidity statistics. An example is a situation in which three victims require chest tubes (two victims require one tube each and one victim requires two tubes), but only two chest tubes are available. The SAVE principles guide providers to place their last two chest tubes into the two victims who need it rather than into the single victim requiring two tubes.

During the triage process, individuals who would most benefit from early transport should be marked as “first out” in case an evacuation opportunity occurs. These would be victims with medical problems readily treatable at a hospital or facility with equivalent capabilities but untreatable and fatal in the field. A patient requiring surgery for intra-abdominal hemorrhage is a common example.
Since nuclear, biologic, and chemical terrorism has become a threat, triage systems have been modified to address these situations. These systems attempt to incorporate the added threats from exposure and contamination into the triage process. One such method for biologic casualties triages many individuals to home observation rather than hospitalization to optimize resource use and to minimize the spread of the infectious agent. In addition, responders need to be protected from secondary contamination or exposure; therefore, part of the triage algorithm should include a risk assessment and determination of whether and what type of personal protective equipment should be donned before patients are assessed. This was illustrated during the 2014 Ebola outbreak when health care providers initiated Ebola exposure screening procedures during initial patient contact before engaging in patient evaluation and treatment. In a “combined event” scenario, such as an incident involving a radiologic dispersion device, rapid patient assessment is critical to prevent patient deaths from traumatic injuries while awaiting medical care from responders concerned about their own health and safety. Also associated with terrorism incidents are large numbers of psychological casualties; those who believe they were exposed but actually were not and those at risk for post-traumatic stress disorder. The emergency plan should include a mechanism to assess and to sort these individuals to assure that they have access to mental health care and also so as not to overwhelm the emergency medical capacity. While performing triage, the emergency clinician should consider the effects of extreme age, underlying disease, and multiple injuries when assessing the potential prognosis for a given patient. Treatment of many nontraumatic emergencies can be accomplished with field interventions that do not consume extensive resources. Therefore, patients with such illnesses should usually be triaged to the treatment area.

Vulnerable Triage Populations

Certain groups of patients, such as children, the elderly, the disabled, and homeless persons, may have special needs that present challenges to routine triage. For example, if a person is too young to follow commands or is deaf, the individual would not be able to respond to a command to walk away from an incident site for reasons that may not indicate severe injury. Triage schemes should attempt to accommodate language and cultural barriers, as well as physical and psychological limitations that result in social or medical vulnerabilities.

Special Triage Categories

To maximize human resources, disaster victims who would normally be triaged to the observation area can be triaged to the treatment area if they possess special skills valuable to the medical team (eg, medical expertise and translation skills). By the increase in the number of functional team members, the effectiveness of the overall response will improve. The guiding principle supports the disaster triage goal of maximizing benefit to the most people.

CARE OF POPULATIONS WITH FUNCTIONAL OR ACCESS NEEDS

Within the general population, groups of unique individuals exist that are at greater risk for injury, death, and property loss resulting from a disaster. These vulnerable populations include children, the elderly, racial and ethnic minorities, the disabled, those residing in institutions such as skilled nursing facilities, and the mentally ill. Challenges in the management of these populations with functional or access needs during a disaster include lack of mobility, tracking of victim movement during evacuations and issues of reunification with responsible family members, inability to understand English or to comprehend instructions issued by local authorities, and poor access to transportation resources. A detailed discussion on the disaster management of these populations is beyond the scope of this chapter but available elsewhere. Those responsible for disaster planning should ensure that policies and procedures are developed that address the unique needs of such groups.

OUT-OF-HOSPITAL RESPONSE

Emergency Medical Services System Protocols

To prepare adequately, hospitals should be familiar with and involved in the development of county or regional plans. For example, some EMS systems use automatic systems such that each hospital may be expected to accept a fixed number of critically ill or injured and minor patients without advanced notification.

Physicians working at hospitals should be familiar with and involved in community disaster management operations, including the function of the emergency operations center. Mutual aid agreements with other hospitals or regions should be considered for situations in which current hospital capacity is exceeded or evacuation is necessary.

Incident Command System

Some form of an incident management system is a standard component of emergency command and control throughout the United States. It provides a flexible management structure on which to organize a response. The federal version, known as the National Incident Management System, is incorporated into the National Response Framework and provides strategic guidance on the United States government’s involvement in disaster response. All states must use an incident management system compliant with the National Incident Management System. By standardizing an organizational structure and using a common vernacular, an incident command system provides a management configuration that is adaptable to events involving a multiagency or multijurisdictional response. At the most basic level, there are five functional elements in the organizational structure: incident command, operations, planning, logistics, and finance. The principles of an incident command system can also be applied to the hospital setting through implementation of a Hospital Incident Command System. With this type of organizational infrastructure and the flexibility to expand and to collapse functions as needed, an orderly and efficient response to any incident can be accomplished. Because hospitals cannot anticipate every contingency, a system such as the Hospital Incident Command System assists with planned improvisation. The Joint Commission standards require use of an incident management system in health care facilities.

Incident Command

The incident commander has overall management responsibility for the incident. Physicians should understand that they are not in charge at the scene of an out-of-hospital incident. In general, nonhospital providers can manage the scene, and physicians should remain at the hospital to provide definitive care. When a physician is on scene, the best way to assist is to ask the incident commander where medical help is most needed.

The incident commander may choose to appoint a command staff to manage public information, safety, and interagency coordination. When an event involves multiple jurisdictions, a unified command is established that coordinates a common and consistent action plan to make the best use of available resources.
Operations Section

The operations section has a chief who is responsible for the management of all incident tactical activities. This section can be expanded and subdivided into branches (eg, law, fire, and medical) and divisions. The operations section also manages the resources assigned to staging areas. For events with a discrete scene, ambulances, personnel, and supplies should be staged outside the perimeter and directed in as needed rather than converging on the disaster site, potentially disrupting activities and blocking the exodus of patients. It is under the operations section that all medical triage and care is provided.

Planning Section

The planning section collects, evaluates, and disseminates information about incident operations and the status of resources. This section also develops incident action plans and conducts planning meetings.

Logistics Section

The logistics section’s chief is responsible for providing facilities, services, and material in support of the incident. This includes procuring equipment and supplies, providing food and medical support, and meeting transportation needs.

Finance Section

The finance section is responsible for maintaining records on personnel and equipment, providing payments to vendors for supplies and use of equipment, and determining the cost of various alternatives for strategic planning.

Organization of the Out-of-Hospital Disaster Scene

The disaster site is organized into several distinct areas. The command post is the nerve center of the operation and contains the incident commander and section chiefs. A staging area for incoming personnel and equipment should be established on the outer perimeter. If air evacuation is needed, a safe landing zone must be identified. A casualty collection point and morgue should be designated. In conjunction with an incident command system, this structure brings order to the response.

PLANNING AND HOSPITAL RESPONSE

Comprehensive Emergency Management

The comprehensive emergency management all-hazard approach to disaster preparedness has been a Joint Commission requirement since January 2001. Comprehensive emergency management consists of four phases: mitigation, preparedness, response, and recovery. Mitigation involves taking actions to reduce the impact of identified hazards. Enhancing the seismic structural design of hospitals is one strategy to mitigate the impact of large earthquakes on the health care system. Training, drills, and cataloging of resources are examples of preparedness activities. Response includes assessment of the situation and coordination of resources. Finally, recovery consists of a return to normal operations and debriefing to critique the response and to provide long-term psychological support to the victims and rescuers.

As required by The Joint Commission, a hospital’s disaster or “emergency management” plan needs to address events that occur both inside (internal) and outside (external) the institution. Because some incidents affect both internal and external opera-

Hospital Disaster Response Plan

A disaster event can disrupt daily, routine hospital functions. This can represent an infrastructure failure (eg, loss of electric power and water) or a threat to the safety of patients and hospital personnel (eg, labor dispute or approaching hurricane). Because the response varies from postponement of elective surgery to facility evacuation, every hospital department needs to participate in the planning process. At a minimum, the disaster plan should clearly delineate the circumstances in which the plan is activated; identify the command structure with defined lines of authority and responsibility; describe a response strategy for each anticipated incident; estimate an incident’s impact on safety and hospital function, providing for evacuation if necessary; and list essential information, such as critical telephone numbers (eg, elevators, key personnel, and pay telephones), community agencies (EMS, police, and public health), and sources of vital supplies (water, oxygen, and drugs).

After plan activation, the primary role of the ED is to assess and to treat individuals with illness or injury. In the absence of casualties, other hospital departments primarily manage disasters that disrupt hospital operations. Nevertheless, the medical director of the ED should continuously monitor the response process.

In the unlikely event that evacuation of the ED is necessary, evacuation routes and relocation destinations that have been planned in advance maximize safety and efficiency. When resources are plentiful, ED patients in critical condition are assigned the highest priority for evacuation and transport. Less ill patients receive a lower priority. When resources are limited (eg, in the event of a large-magnitude earthquake), the reverse strategy applies. The least critically ill patients receive the highest priority for evacuation.

Another scenario would be an event occurring in the community that results in a sudden influx of patients requiring emergency care at hospitals. This type of incident has no direct impact on hospital structural integrity or function. However, the need to rapidly increase surge capacity may require implementation of different patient management strategies (ie, temporary creation of alternate care sites on hospital grounds). Participation in the planning and execution of the hospital disaster response is an important administrative responsibility. Available data guiding development of disaster strategies are incomplete, but an effective disaster response can be created by reviewing the essential components of disaster plans and the previous experience of hospitals. A member of the ED must have a leadership role in the planning and implementation of the disaster plans.

Basic Components of a Hospital Comprehensive Disaster Response Planning Process

Interdepartmental Planning Group

The interdepartmental planning group has the responsibility for hazard identification and disaster preparedness activities. The process of conducting a hazard vulnerability analysis is complex, but templates such as the one created by the Kaiser Foundation Health Plan may be informative. Frequently referred to as the disaster or emergency preparedness committee, it is composed of representatives from all departments vital to the hospital’s response, including administration, medical staff, nursing, safety, security, ED, and engineering. Additional input may occasionally be necessary from outside agencies (eg, fire department, hospital suppliers of goods and services, and EMS agency).
The committee should be structured to ensure that the plan is properly constructed, tested, and executed. Hospital resources are needed to support the planning process and testing of the plan, and a detailed educational program should exist for all affected hospital staff.11,13

Resource Management

A full inventory of the hospital’s resources is necessary. In addition to equipment, space, and personnel within the institution, potential support from outside the hospital should be sought. It is also necessary to develop contingency plans to compensate for lost resources (e.g., failure of hospital computers during a power outage or cyber-attack). Augmentation of such resources is critical to the successful increase of the hospital’s surge capacity.

Strong relationships with community agencies (e.g., fire department and regional EMS system) are important to ensure a coordinated disaster response. Hospitals located near companies using large amounts of hazardous materials are required by Title III of the Superfund Amendments and Reauthorization Act to participate in local emergency planning committees (LEPCs).11

Command Structure

An organized system establishing lines of authority and decision responsibility should be in place. This system needs to designate a command center where the disaster response can be coordinated and create a clear chain of command. This prevents confusion if certain individuals are missing, a common situation on nights and weekends or in cases of a community-wide disaster during which hospital personnel may become victims. The command center should contain sufficient equipment to support command and control functions, even if the center must be moved as a result of hospital damage. Implementation of the Hospital Incident Command System or similar management structure will support all such requirements.

Media

The media can be an important source of information but can also significantly disrupt the hospital’s disaster response. Therefore, arrangements should be made in advance for a designated individual to coordinate all media interactions and for these briefings to occur in a designated location. Frequently referred to as the public information officer (PIO), media coordinators should inform reporters of the time they will receive their next update so that they do not intrude on response operations while trying to inform reporters of the time they will receive their next update. A strong media liaison can facilitate dissemination of important information to the public, such as that no blood shortage exists so that individuals refrain from coming to the hospital to donate blood. In fact, crisis and emergency health risk communication is now an important part of managing the disaster response and can have a significant impact on the public’s perception of events. Individuals designated the media coordinator should be familiar with the basic principles of emergency health risk communication. Security should be involved in managing the media response to the hospital and in preventing media from interfering with triage and treatment of patients.

Communication

Communication systems are probably the most important but also most vulnerable component of a disaster plan. Redundant systems are essential. Those responsible for mobilizing the emergency response require access to at least one other communication system besides the telephone (which is frequently one of the first systems compromised during a disaster). Two-way radios are often used, as are pay telephones, independent fax lines, and cellular phones. Another option is the use of satellite phones and wireless handheld devices to transmit email messages. Recent advances in communication technology exemplified by Facebook and Twitter show promise. Survivors of the 2011 Japan earthquake used these techniques to provide early information to the outside world on conditions within the disaster zone.12 Runners are also useful for intrahospital communication if all else fails.

Personnel

The disaster plan should include a roster of all critical positions and personnel and establish a reliable method for their mobilization. Several individuals should be assigned to each position in case some personnel cannot be reached. A protocol for managing volunteers is also crucial. A large group of uncontrolled volunteers descending on a hospital (“convergent volunteerism”) can be as disruptive as the disaster.

CREDENTIALING OF VOLUNTEER HEALTH PROFESSIONALS (ESAR-VHP) ATTEMPTS TO ADDRESS THIS PROBLEM. IT WILL PROVIDE A SYSTEM FOR CREDENTIALING OF VOLUNTEER HEALTH CARE PROVIDERS IN ADVANCE OF A DISASTER SO THAT THEY WILL HAVE EMERGENCY PRIVILEGES SHOULD THE NEED FOR THEIR SERVICES ARISE. THERE REMAIN SIGNIFICANT CHALLENGES WITH SUCH A SYSTEM, INCLUDING WHETHER SUFFICIENT NUMBERS OF PROVIDERS WILL PARTICIPATE, HOW FAST THEY CAN DEPLOY, HOW WELL QUALIFIED THEY WILL BE, AND WHETHER THEY WILL HAVE COMPETING OBLIGATIONS DURING A DISASTER. AN ALTERNATIVE SYSTEM THAT PERMITS HOSPITALS TO RECOGNIZE EACH OTHER’S CREDENTIALING PROCESS THROUGH A SHARED DATABASE SHOWS PROMISE AND HAS BEEN ENDORSED BY A PUBLICATION FROM THE AGENCY FOR HEALTHCARE RESEARCH AND QUALITY. NOT ONLY WILL THIS ALTERNATIVE SYSTEM FACILITATE PARTICIPATION BY MOST HEALTH CARE PROVIDERS, BUT IT ALSO PERMITS HOSPITALS TO GRANT EMERGENCY PRIVILEGES WITHIN MINUTES AFTER A DISASTER.

Patient Management

A systematic approach to patient management is necessary to maximize resources. This includes protocols for decontamination, triage, patient prioritization, evacuation, and control of patients’ families. Alternative use of hospital facilities should be anticipated, such as the conversion of a parking lot into a clinic area for suturing of lacerations or a decontamination zone. Provisions for patient identification and treatment documentation are also important to facilitate federal and third-party reimbursement at the conclusion of the disaster.

Training Exercises

Disaster exercises are one of the more effective ways of familiarizing hospital staff with their responsibilities. All hospital departments should participate, and community agencies should be involved. The Joint Commission requires two drills a year; these should mimic incidents that are likely to occur. Methods to assess the effectiveness of these exercises as measures of overall hospital disaster preparedness are improving.16

REVIEW OF HOSPITAL AND COMMUNITY DISASTER RESPONSE EXPERIENCE

Disaster plan implementation is complex and difficult. Knowledge can be gained from review of previous disaster response experiences and publications, resulting in improved implementation strategies. The following discussion highlights potential challenges.
Focal Disasters

Most disasters experienced by hospitals are focal in nature. Hospital function is typically unimpaired. The majority of problems encountered relate to creating surge capacity for the sudden increase in volume and acuity of arriving patients, or for those with illnesses not usually treated at that facility (eg, burns, radiation exposure, and severe acute respiratory syndrome).

Hospitals frequently experience difficulty in effectively using and interfacing with community resources. Field triage should allocate patients rationally, and transfer agreements must be in place to facilitate interhospital movement of patients and evacuation of patients to alternate care sites.

Peter access must be controlled. During the Loma Prieta earthquake in 1989, a news helicopter occupied a nearby community hospital’s only landing zone, preventing the possibility of landing a medical helicopter.

Redundant communication systems must be in place. Typical backup systems to the telephone are radios and cellular phones, but the frequencies can be overloaded in both systems. Use of cellular phones for text communication may offer another solution. Two-way radios are reliable and should be part of the communications network. Satellite phones are also an option.

Catastrophic Disasters

In a large-scale disaster, paramedics may be unavailable to assist in patient transfers or hospital evacuations. DMATs and urban search and rescue teams will deploy, but their time to arrival on scene may be variable. Each individual hospital may need to remain self-sufficient for 48 to 72 hours or longer.47 Generator problems are frequent; they either fail altogether (as they did during the Loma Prieta earthquake) or supply insufficient power to meet emergency needs (as during the Northridge earthquake). Evacuation plans must not require elevators for this reason.

Telephone service will cease as lines are disrupted or deliberately restricted by the phone company. Cellular phones may function within a local area, but failure is likely if more distant sites within the city are dialed. Hospital radios designated for disaster use should have the hardware secured to prevent earthquake damage.

Under catastrophic conditions, mobilization of personnel is more difficult. Because telephone communication is unreliable, at least one additional system to contact personnel at home should be in place. An alternative is to institute an automatic response system, in which personnel report to the hospital or another location when communications are impaired.

After earthquakes or explosions, immediate access to structural engineers is important. In the Northridge earthquake, eight hospitals in the Los Angeles area sustained enough damage to force evacuation of at least one patient. Four institutions completely evacuated their facilities in the first 24 hours, including two hospitals that met the most current structural earthquake standards. Further structural damage was subsequently identified, and two additional hospitals were forced to evacuate completely in the next 2 weeks. Ultimately, four of these hospitals were permanently closed and demolished.

Hospitals are also vulnerable to hurricanes. In a study of hurricane Rita’s (2005) impact on regional hospitals in Texas and Louisiana, seven hospitals were forced to evacuate patients.12 Significant problems included prolonged loss of power, potable water, and staff. It was also difficult to obtain vehicles for transportation of patients to other facilities. Nonmedical vehicles were sometimes used to evacuate stable patients.

Catastrophic earthquakes can cause extensive casualties, including large numbers of patients with crush syndrome and lacerations. Up to 90% of victims with serious but survivable injuries are rescued by local responders and volunteer citizens in the first 24 to 48 hours. Therefore, special medical teams, such as DMATs and urban search and rescue teams, may not significantly affect survival from acute injuries if they arrive after more than 48 to 72 hours. The traditional view holds that deploying field hospitals to distant disaster zones does not improve outcomes. The results reported by the Israeli Field Hospital after deployment to the Haitian Earthquake may change this.17 If hospitals are not functional and no backup plan exists, immediate advanced medical care will not be available, and many people will die. Therefore, planners should include a backup system to provide medical care at alternate nonhospital care sites.

Need for Local Response

Currently, it is not possible for outside assistance to arrive in force during the crucial first 48 hours after the event. Therefore, an alternative source of rapidly available, sophisticated medical care is necessary. It appears this is best provided by local responders who can begin caring for patients soon after the event. The Medical Disaster Response Project is the most advanced model of a local medical response to such a disaster. Developed by emergency clinicians in southern California, the Medical Disaster Response Project has two components: (1) training of health care providers in the management of disaster victims under austere conditions and (2) placement of sophisticated medical supplies at designated sites within the community. Under this plan, victims could receive rapid, advanced medical care from surviving volunteer health care providers even if hospitals were destroyed. The current Strategic National Stockpile is modeled after components of this plan. In addition, it was used as a major source document for the development of the Medical Reserve Corps.

Toxic Disasters (Hazardous Material)

Hospitals in the vicinity of major chemical industries, transportation corridors, or probable terrorist targets (eg, major theme parks or nationally symbolic buildings) should be aware of potential hazards from incidents involving chemical and radioactive substances. Such facilities should be prepared to decontaminate large numbers of individuals exposed to these hazardous substances. Effective decontamination of victims and the need for safety measures on the part of rescue personnel to prevent secondary contamination are critical. Decontamination equipment should be stored near the ED and the staff trained in its use. This location should be known to personnel. When such an emergency occurs, there is little time to search the hospital for the necessary supplies.

Ideally, patients contaminated with hazardous chemicals should first be brought to a designated decontamination area containing a warm-water shower with a container to hold drainage water. Victims should remove all clothing. Clothing and valuables are bagged, identified, and stored. Contaminated patients should never be brought into regular patient care areas due to the danger of contaminating other patients, hospital staff, and equipment. In 1994, paramedics unsuspectingly transported a patient contaminated with a degradation product of dimethyl sulfoxide to an ED in Riverside, California. Before the presence of the hazardous material was detected, six health care workers were exposed, including an emergency clinician. The emergency clinician experienced a near-fatal exposure and required intubation and an extensive stay in the hospital’s intensive care unit. Uncontrolled spread of the toxin resulted in evacuation and temporary closure of the ED.

Closing off air intake vents by hospital personnel is appropriate for rooms containing contaminated patients so that toxic products do not enter the ventilation system and circulate to other areas of the hospital. Rescue personnel and hospital staff should be
protected by gowns, gloves, and masks and, if necessary, supplied air respirators. The goals are to reduce the initial level of external contamination, to contain the contamination that remains, and to prevent further spread of these potentially dangerous substances to other patients and staff members (secondary contamination).

**CHEMICAL, BIOLOGIC, RADIOLOGIC, NUCLEAR, AND EXPLOSIVE TERRORISM**

In addition to the familiar threat from hazardous materials, there is another challenge: a potential attack by terrorists using biologic, radiologic, or chemical weapons (see Chapter 193). Although somewhat similar to hazardous materials situations, management of patients exposed to weapons of mass destruction (WMD) requires additional knowledge and skills. Expertise in the management of patients attacked with unconventional weapons is important, but emergency clinicians should also be familiar with treatment of blast injuries. High-explosive events, including suicide bombers, remain the most probable type of terrorism. The most likely radiation source used by terrorists will probably not come from the detonation of a nuclear weapon. Instead, simple radiologic devices, such as those used by hospitals for radiation therapy, are believed to be the source of choice. They do not explode and give no warning of their presence. Terrorists can also dismantle such devices and incorporate the radioactive source into an explosive radiologic dispersion device (“dirty bomb”). Therefore, providers should recognize the presentation of patients suffering from radiation exposure to make the diagnosis. In addition to damage from radiation, these casualties may also suffer blast injuries. Initial treatment of such victims, if they are critically injured, should address stabilization of the blast injuries first before the radiation exposure is considered. Patients who are irradiated but not externally or internally contaminated pose no threat to ED personnel.

One of the greatest challenges with respect to WMD is the detection of biologic weapons. Patients exposed to biologic agents often initially present with vague symptoms associated with influenza-like illnesses. Decontamination is not a priority unless the exposure is immediate; standard precautions are generally sufficient. Unlike radiologic or biologic weapons, chemical agents produce symptoms quickly. The challenge is decontamination and treatment. Approximately 80% of mass casualty decontaminations are performed at hospitals. Therefore, hospitals should be prepared to decontaminate patients outside the ED. Personal protective equipment is also essential for responders and hospital “first receivers” due to the risk of exposure during the decontamination process.

**DISASTER STRESS MANAGEMENT**

Emergency health care providers experience high levels of stress when responding to the needs of disaster victims. If this excessive stress exceeds the capacity of normal coping mechanisms, it can potentially interfere with job performance and produce symptoms, including depression, sleep disturbances, increased use of alcohol and drugs, irritability, and anxiety. Post-traumatic stress disorder can result. In an attempt to reduce the psychological impact of these events on medical responders, various therapeutic techniques have been introduced throughout the years and are collectively known as critical incident stress management. This formal process of resolving emotional conflict using mental health professionals is now widely practiced. In general, the longer the delay between exposure to the critical incident and subsequent psychological intervention, the smaller is the chance for a successful outcome. Therefore, the critical incident stress management process is designed for rapid implementation. During the incident, stress management staff or even a colleague can provide on-scene intervention. The goal is to assist the health care worker in regaining emotional control by facilitating communication of feelings and reactions through listening and support.

If a critical incident has profoundly affected participants and if symptoms are still present many hours later, urgent assistance is provided in the form of defusing. The critical incident defusing process is coordinated by mental health and peer support staff and focuses on information and venting of emotions. This process often takes place away from public view to protect confidentiality. If the psychological stress is severe, the process transitions to formal care provided by psychiatrists or psychologists. Data from previous experiences suggest that such intervention can assist providers in maintaining job performance and satisfaction.

In addition to disaster health care providers, the victims themselves can suffer significant psychological trauma. Rapid identification of such individuals is a priority and can be facilitated by use of a recently developed psychological triage algorithm known as PsySTART. The tool itself has been previously validated and, in a recent trial, appears to assist health care workers in rapidly identifying patients who may benefit from acute psychological intervention.19

**DISASTER MANAGEMENT AND RESPONSE ORGANIZATIONS WITHIN THE UNITED STATES GOVERNMENT**

**Department of Homeland Security**

The Department of Homeland Security (DHS), a cabinet-level department formed after the terrorist attacks of September 11, 2001, is the federal government’s lead organization for emergency management activities in the United States. The Federal Emergency Management Agency (FEMA) was incorporated into DHS and retained its name. DHS has a coordinating responsibility for the entire spectrum of disasters irrespective of their size or etiology. DHS assists state and local organizations to mitigate, to prepare for, to respond to, and to recover from emergencies and is a source of funding for these endeavors. In 2003, the President directed that DHS develop a National Incident Management System and a National Response Plan. Existing federal plans, including the National Response Plan, were then incorporated into the National Response Framework. The National Response Framework includes 15 Emergency Support Functions (ESFs). Each has a primary (lead) federal agency and many supporting agencies. ESF #8 is entitled Public Health and Medical Services and is of key importance to the health care community. The primary agency is the Department of Health and Human Services (DHHS). Examples of functions within ESF #8 include coordination of health care personnel, supplies, pharmaceuticals, surveillance and reporting, and mass fatality management.

**Urban Search and Rescue (ESF #9 of the National Response Framework)**

When a building collapses because of an earthquake, terrorist bombing, structural failure, or other reason, various challenges confront rescue and medical personnel. Some victims require field amputations to facilitate extrication, and use of urban search and rescue teams and effective emergency medical care may improve the outcomes of such lifesaving efforts. The role of urban search and rescue teams has recently been questioned and the cost effectiveness of their interventions remains unclear.19 This national system of multidisciplinary task forces is designed for rapid deployment to the sites of collapsed structures. The medical team’s responsibilities include caring for task force members,
victims recovered by search and rescue activities, and the search team's dogs. There are also WMD urban search and rescue teams trained by FEMA to respond to nuclear, biologic, and chemical terrorist attacks.

**Department of Health and Human Services**

On December 19, 2006, the President signed the Pandemic and All-Hazards Preparedness Act (S. 3678) into law and created a new position, the Assistant Secretary for Preparedness and Response (ASPR), within DHHS. The office of the ASPR oversees the department’s responsibilities for emergency preparedness and response activities, including the National Disaster Medical System (NDMS) and the Hospital Preparedness Cooperative Agreement Program, the coordination of the Medical Reserve Corps, ESAR-VHP, the Strategic National Stockpile, and the Cities Readiness Initiative.

**National Disaster Medical System**

NDMS is a federally coordinated initiative designed to augment the emergency medical response capability of the United States in the event of a catastrophic disaster. This system is a cooperative program of four departments in the federal government: the Department of Defense (DoD), DHHS, DHS, and the Department of Veterans Affairs (VA). Although oversight of NDMS has moved between federal departments, DHHS currently has the lead for this program. NDMS provides an interstate medical mutual aid system linking the federal government, state and local agencies, and private sector institutions to address the medical needs of victims of catastrophic disasters. The three distinct NDMS elements focus on field medical response, patient transport, and definitive care. Its field medical response element includes dozens of volunteer civilian DMATs that supplement the local medical infrastructure, as well as disaster mortuary operations response teams (DMORTs), emergency medical services, and various specialty teams (eg, surgical teams).

In a disaster, NDMS is activated when state resources are overwhelmed and the governor makes a request for federal assistance. The DMATs and other teams must meet specific NDMS standards. Throughout the NDMS, emergency clinicians are taking key roles in defining training standards, the deployment of clinical services, and the administration of field operations and in developing the concept of a civilian-federal disaster response capacity during national emergencies. DoD manages patient transfers and provides patient transport from an impacted area to a designated definitive care site. The VA and DoD’s Federal Coordinating Centers (FCCs) manage the provision of definitive care by directing patients requiring treatment to health care facilities that have Memoranda of Understanding with NDMS.

**Department of Veterans Affairs**

VA has not traditionally been regarded as a disaster response entity. However, one of VA’s four legally mandated missions is emergency management. A unique feature of VA is that its facilities and personnel are situated nationwide, and these are used to support federal health and medical assistance to state and local governments during disasters. VA has highly trained specialty personnel who can support disaster medical activities. In addition to the vast pool of human resources, VA provides large amounts of the pharmaceuticals and expendable supplies for on-site disaster support. VA support is coordinated through DHS and DHHS, as the lead federal agency for health and medical response. In addition to VA’s role in the federal response to disasters, as the largest integrated health care system in the nation, it has a well-developed hospital emergency management program. Professional emergency managers are located at VA medical centers throughout the country. They also manage the majority of NDMS FCCs. The VA develops a number of emergency management planning and operations tools. Many of these are open source and available to the public.

**Future Directions**

The field of disaster medicine has become a major subspecialty within emergency medicine, and standing committees and membership sections for disaster medicine are now organized within the ACEP and the Society for Academic Emergency Medicine. There are also numerous national and international forums for the presentation of disaster medical research results. Since the ACEP first defined a disaster medicine curriculum suitable for residencies and fellowships, a number of disaster medicine fellowships and advanced degree programs have been established in the United States and elsewhere. Standardized all-hazard disaster core competencies and associated curricula are being developed and promulgated. Disaster medicine textbooks and journals are increasing. In the 21st century, disaster medicine will continue to develop as a professional activity and unique academic specialty. Increasing and enhancing disaster medicine research activity will be crucial to sustaining this trend. Finding sustainable funding sources remains one of the most significant challenges.
Comprehensive emergency management consists of four phases: mitigation, preparedness, response, and recovery. Mass casualty planning should account for the fact that traditional transport and communications systems will break down. Field personnel should be specifically trained in mass casualty triage and stabilization because austere field conditions change management strategies. All plans must protect caregivers and rescue personnel.

Critical incident stress management may be highly desirable after an event and should be planned for in advance. Psychological triage tools, such as PsySTART, may help. Planners should establish and exercise a hospital-based incident management system. Disaster planning needs to include policies to address the needs of vulnerable populations, such as children, disabled, and the elderly.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
CHAPTER 192: Questions & Answers

192.1. Which of the following statements is true regarding applications of Secondary Assessment of Victim Endpoint (SAVE) triage guidelines?

A. It is applicable to day-to-day hospital operations.
B. Outcome expectations are theoretically based.
C. Patients are sorted into one of four categories.
D. The system provides detailed management of psychogenic cases.
E. Triage decisions are based on field outcome expectations.

Answer: E. The SAVE system is designed specifically for care in an austere environment. It triages patients into (1) those who will die regardless of treatment, (2) those who will live regardless of treatment, and (3) those who would benefit from austere intervention. The triage decisions are based on field outcome expectations from existing survival and morbidity statistics.

192.2. Which of the following best describes the National Disaster Medical System (NDMS)?

A. It does not include private sector institutions.
B. It does not involve the Department of Veterans Affairs (VA).
C. It is military based.
D. The Department of Health and Human Services (DHHS) has oversight.
E. The medical response element consists of Department of Defense (DoD) personnel.

Answer: D. The NDMS is a federally coordinated initiative that is a cooperative program between the DoD, VA, DHHS, and Department of Homeland Security (DHS) with oversight provided by DHHS. The NDMS provides a system of coordinated mutual aid agreements among federal, state, local, and private institutional entities for resource and personnel provision in times of disaster. The medical response element includes dozens of volunteer civilian medical teams that supplement the local medical infrastructure.

192.3. Which of the following statements is true regarding disaster response?

A. Critical incident stress debriefing is best conducted 1 or 2 weeks after the event.
B. Medical resupply systems are the most vulnerable component of a disaster plan.
C. One of the Department of Veterans Affairs (VA) system's four legally mandated missions is emergency management.
D. The Federal Emergency Management Agency (FEMA) has a coordinating responsibility for the entire spectrum of disasters.
E. The Joint Commission mandates deal only with disasters within the hospital.

Answer: C. One of the VA health system's four mandated missions is emergency management. Although controversy exists, critical incident stress debriefing, if used, should be implemented as early as possible. The Department of Homeland Security (DHS) has full-spectrum disaster coordinating responsibility. Communications systems are likely the most vulnerable systems. The Joint Commission mandates deal with plans and preparations for disasters within the entire community as well as within the hospital.

192.4. Which of the following statements is not a feature of emergency management?

A. During simple triage and rapid treatment (START) triage, two interventions may be performed: opening an airway and controlling external hemorrhage.
B. Health care facilities should perform a hazard vulnerability analysis to assess community risks.

Answer: A. During simple triage and rapid treatment (START) triage, two interventions may be performed: opening an airway and controlling external hemorrhage.
C. PICE is a conceptual framework to describe disasters and stands for “potential injury-creating event.”

D. The four phases of comprehensive emergency management (CEM) are pre-event, event, post-event, and baseline.

E. Worldwide morbidity and mortality from disasters is increasing, in part due to increases in population density.

Answer: D. The four phases of CEM are mitigation, preparedness, response, and recovery. These phases represent a continuum over time, and more than one phase may be in effect at the same time (eg, even during the response phases, recovery actions may take place.)
CHAPTER 193

Weapons of Mass Destruction

Carl H. Schultz | Kristi L. Koenig

**PRINCIPLES**

Besides managing the injuries and illnesses from common disasters such as earthquakes and airplane crashes, emergency clinicians should also have competence in treating victims generated by terrorist attacks with nuclear, biologic, chemical, or high-energy explosive weapons. Conventional explosives remain the most common weapon used by terrorists; however, the risk from nuclear, biologic, and chemical agents may increase over time. The nomenclature for these weapons is not standardized. The military uses the acronym CBRNE, pronounced “see-burn-ee,” referring to chemical, biologic, radiologic, nuclear, and explosive agents. This chapter uses *weapons of mass destruction* (WMD) because of its wide acceptance and familiarity.

The results of an attack with WMD, although admittedly of low probability, are potentially catastrophic. According to a World Health Organization (WHO) estimate, 50 kg of anthrax spores aerosolized above a city of 5 million people would result in 100,000 deaths, with an additional 150,000 people seriously infected. The cost of managing 100,000 cases of anthrax exposure is estimated at between $6.4 and $26.2 billion. These types of estimates have led to authorities establishing emergency preparedness as a priority.

Children are particularly vulnerable to these weapons. They breathe at a faster rate than adults do, increasing their relative exposure to aerosolized agents. Some chemicals, such as sarin, are heavier than air, so they tend to accumulate at the level where children are more likely to inhale them. Children have a greater surface area–to–volume ratio and their skin is thinner. This makes them more susceptible to agents that act on or through the skin. They have smaller fluid reserves and higher metabolic rates. Therefore, they are more vulnerable to dehydration from vomiting and diarrhea and suffer increased toxicity from a given exposure, such as to radioactive iodine ($^{131}$I).

The use of biologic and chemical agents dates to biblical times, although the threat from radiation and nuclear detonation is relatively new. Assyrians poisoned the wells of their enemies with rye ergot in the 6th century BC. The Mongols catapulted bodies infected with bubonic plague over the walls of Kaffa in the 14th century. The British Army gave American Indians blankets taken from individuals infected with smallpox during Pontiac’s Rebellion in 1763. During World War I, the Germans effectively used chlorine and mustard gas against the advancing Allied armies. The Japanese killed hundreds to thousands of Chinese citizens with bubonic plague during World War II by spraying towns with fleas infected with *Yersinia pestis*. Saddam Hussein used a mustard agent against the Iranians during the Iran-Iraq War in the 1980s. Most recently, the Syrian government attacked cities within its own country using chemical nerve agents.

The use of WMD has been predominantly by the military during times of conflict. Toward the end of the twentieth century, however, the use of these agents has taken an ominous turn. Nonaffiliated groups have begun using WMD directed at civilians to achieve political ends. The Bhagwan cult sprayed salad bars in Oregon with *Salmonella* in an attempt to influence an election in 1984. The Aum Shinrikyo used the nerve agent sarin in an unsuccessful 1994 assassination attempt on three judges in Matsumoto, Japan. This same group used sarin again in the 1995 Tokyo subway attack that killed 11 people. The United States experienced multiple anthrax hoaxes during 1997 and 1998, motivated by personal, political, or other agendas. Terrorists initiated an actual anthrax attack using the United States mail in 2001 that resulted in 11 deaths. No one has yet used radiologic or nuclear devices in a successful mass terrorist attack, but at least one attempt has occurred. In addition, several highly radioactive sources have been stolen from American medical facilities, and a Russian dissident, Alexander Litvinenko, was assassinated with a radiologic agent (polonium–210) in 2006.

Many agents are potential candidates for weaponization, and some represent a substantial risk (Box 193.1). Management strategies for patients exposed to WMD are frequently similar to strategies for hazardous materials exposure. However, several features associated with WMD make these events unique (Box 193.2). Additional knowledge and skills are required in the evaluation and treatment of WMD victims. These plans represent only one small part of an overall comprehensive emergency management strategy for all hazards (see Chapter 192). Names of departments, bureaus, and agencies that can assist with planning and response to WMD events are listed in Table 193.1.

**SPECIFIC DISORDERS**

**NUCLEAR AND RADIOLOGIC DEVICES**

**Principles**

Terrorists selecting radiation as a means to inflict casualties are unlikely to use nuclear weapons. These devices are heavily guarded, difficult to move because of their size and weight, and easy to detect. Although Russia acknowledges that 50 to 100 of its 1-kiloton “suitcase” nuclear weapons are missing, the problems of purchasing, moving, and detonating these devices are formidable. Sabotage at nuclear power stations is possible, but given tight security, multiple safety systems, and thick concrete housings surrounding the reactors, the threat is probably low.

Instead, simple radiologic devices, such as those used by hospitals for radiation therapy, are thought to be the source of choice. These sources are plentiful. They do not detonate on their own and give no warning of their presence unless they are dispersed by a conventional explosive (radiologic dispersal device). Thefts of radiotherapy sources have occurred in the United States. Accidental dispersion from a stolen hospital therapy source in Brazil resulted in the screening of 112,000 people for contamination. A total of 249 people were found to be exposed—four of whom ultimately died. Placement of such a device at an information kiosk in a crowded mall during a busy holiday shopping season would silently expose countless persons to significant radiation.
CHAPTER 193  Weapons of Mass Destruction

Contaminated patients are more challenging, and early involvement of the radiation safety officer is critical. This individual evaluates the degree of the victim's contamination and monitors radioactivity levels throughout the decontamination process. Internally contaminated patients present a therapeutic challenge because they have radioactive material inside their bodies (e.g., lungs and gastrointestinal tract) or incorporated into their cells. They should be placed in an isolation room where all secretions and body fluids can be collected. Various medications are available for administration to internally contaminated patients and can limit uptake or facilitate removal of certain radioactive elements. These medications include Prussian blue (Radiogardase) for cesium and thallium ingestions and diethyletriaminepentaacetic acid (DTPA) for plutonium exposure.

Health care providers can receive assistance by calling the Radiation Emergency Assistance Center/Training Site (REAC/TS; http://orise.orau.gov/reacts/) at 865-576-3131 (emergency number: 865-576-1005).

Externally contaminated victims have radioactive material on their skin or clothing and are decontaminated by removal of clothing and washing with soap and water. Washing by protected personnel should continue until monitoring by the radiation safety officer demonstrates the absence of radioactivity. If wounds are present, they are decontaminated first. After the wounds are covered with a sterile, waterproof dressing, the remaining skin is washed. Hospitals should be prepared to decontaminate patients because historical data suggest that up to 80% of patients do not receive this intervention before arrival. Decontamination before hospital entry is crucial because these individuals can expose caregivers to radiation and contaminate the entire hospital through the ventilation system. Removal of clothing and covering

Clinical Features

Ionizing radiation, regardless of its type, causes injury at the cellular level, usually by damaging DNA. Rapidly dividing cells are the most sensitive. Patients have symptoms within hours to days, depending on the dose. Common syndromes associated with radiation exposure include dermal burns, bone marrow failure, and gastrointestinal dysfunction (e.g., vomiting and gastrointestinal bleeding) (see Chapter 138). Reviews of medical treatment for radiologic casualties can be found elsewhere.4

Management

A basic emergency department (ED) radiation protocol should address decontamination, triage, staff safety, personal protective equipment (PPE), and diagnostic procedures that emphasize radiation monitoring. Victims presenting to the ED will suffer from three types of exposure: irradiation, internal contamination, and external contamination. Irradiated victims have been exposed to a beam of radiation, similar to someone undergoing a chest x-ray examination. They are not radioactive and pose no threat to ED personnel.

### BOX 193.1

**Potential Agents of High Concern for Use as Weapons of Mass Destruction**

**CHEMICAL**
- Nerve agents
  - Sarin
  - Soman
  - Tabun
  - VX
  - Mustard agent

**BIOLOGIC**
- Anthrax
- Plague
- Smallpox
- Botulism
- Viral hemorrhagic fever
- Tularemia

**RADIOLOGIC**
- Simple device
- Dispersal device

### BOX 193.2

**Features of Weapons of Mass Destruction Threat**

- Fear of unknown or unfamiliar
- Lack of training for hospital personnel
- Lack of equipment, including personal protective equipment (PPE) and diagnostic aids
- Potential for mass casualties
- Psychological casualties
- Crime scene requiring evidence collection and interaction with law enforcement
- Potential for ongoing morbidity and mortality (dynamic situation)
of the head with a surgical cap can reduce contamination by 80% to permit stabilization in the decontamination unit, but complete decontamination should occur before exposure of unprotected staff if the patient’s medical condition permits.

Initial triage of radiation casualties is based on their overall pathologic condition, not on exposure.1 Even patients who have received a lethal dose of radiation do not die immediately as a consequence of the ionizing exposure. Therefore, a patient in acute distress from a myocardial infarction or urosepsis would be triaged ahead of a radiation victim with stable vital signs, regardless of the dose received. If a radiation casualty also suffers a severe injury or illness, immediate intervention is required. Most of the immediate morbidity and mortality associated with a radiologic dispersion device is related to traumatic injuries from the explosion and not to radiation exposure.

In addition to contaminated patients, the radiation safety officer is responsible for monitoring of the exposure of hospital staff. All personnel involved in the care of contaminated patients should wear dosimeters, which measure the amount of radiation received by the wearer. The safety officer tracks the amount of radiation received by each staff member and can remove a health care worker from the area if the exposure is too high. Radiation monitoring is complex, and the radiation safety officer should be involved as early as possible. Hospitals should consider conducting disaster drills that include casualties suffering radiation injuries.

Although many radioactive elements are candidates for use in a terrorist attack, 131I and related isotopes deserve additional discussion because of heightened interest. 131I is found only after a nuclear detonation or in reactor fuel rods. Although it is not impossible, the probability that terrorists could tap either of these sources is very small. The use of 131I in a radiologic dispersal device is unlikely because of its short half-life (8 days). Even if such a device could be made, it is extremely unlikely that the radiologic dispersal device could disperse sufficient radioactive material to pose an acute health hazard. Given these facts, the probability that any significant exposure of the population (especially children) to 131I will occur is equally small. The large number of childhood thyroid cancers that occurred after the accident at the Chernobyl nuclear power plant resulted, to a significant degree, from situations that will not occur in the United States. These include delayed reporting of a breach in the reactor containment vessel preventing timely evacuation of all exposed populations, failure to effectively quarantine contaminated milk and vegetables, and significant iodine deficiency in the exposed population. The risk to children in communities surrounding the Fukushima nuclear power plant is also an issue that will require long-term monitoring. Nonetheless, concern about treatment to prevent thyroid cancer after potential exposure to 131I remains. Current recommendations for treatment with potassium iodide, which blocks uptake of 131I by the thyroid, are listed in Table 193.2. Caveats for use of this table include increasing the amount of potassium iodide for adolescents approaching 70 kg to the adult dose (130 mg) and monitoring thyroid-stimulating hormone and free thyroxine (T4) levels in neonates when possible. Non-pregnant adults older than 40 years old are unlikely to benefit from this intervention.

### BILOGIC WEAPONS

#### Principles

By convention, biologic weapons are divided into three groups: bacteria, viruses, and toxins. A characteristic shared by these agents is their ability to be dispersed as an aerosol. Because this is the most effective means to expose a large population, aerosol dispersal is the route that terrorists would most likely use to deploy such weapons. Victims, unaware of the exposure to a biologic weapon, present to the ED with nonspecific influenza-like respiratory signs and symptoms. Dermal contact and ingestion are also potential pathways for exposure, and some agents are effective by these routes. People infected in the 2001 United States anthrax attack were inoculated through aerosol and dermal exposures.1 However, it is logistically more difficult to produce large casualty numbers by nonrespiratory portals of entry, so agents spread primarily by injection or through the gastrointestinal tract are less likely candidates for wide deployment. If the goal is to disrupt the economy or to spread fear among the population, then almost any type of release will suffice, whether or not people actually die.

#### Clinical Features

Patients exposed to biologic agents usually present with vague symptoms associated with an influenza-like illness.2,8 Unless a biologic attack is announced or suspected, the ED staff may not realize that they are treating victims. It is not always possible to distinguish natural occurrences from engineered outbreaks of diseases. Examples of non-terrorist related occurrences of anthrax include cutaneous disease in intravenous heroin users in Europe, an outbreak of cutaneous anthrax in Bangladesh in 2010 with more than 400 cases, and isolated infections in drum makers after using contaminated animal hides. Because of the challenges in identifying the true etiology of acute events, personnel should be vigilant and at least consider the possibility, especially when warning signs are present (Box 193.3). For example, large numbers

#### Signs Suggesting Biologic Weapon Deployment

**SYNDROMES**

- Pulmonary symptoms, pneumonia
- Rashes
- Sepsis syndrome
- Influenza symptoms

**EPIDEMIOLOGY**

- Multiple, simultaneous events
- Dead animals
- Large numbers of patients with high toxicity and death rate
Management

Several infectious agents with potential for use as biologic weapons can spread in a hospital environment. Examples include Ebola and smallpox. Hospitals need protocols for PPE and patient isolation to ensure a safe environment. Fortunately, such protocols are similar to those applied to other infectious diseases (Box 193.4) in non-terrorist events (eg, the 2014 Ebola outbreak). For example, implementation of such precautions is credited with halting of the in-hospital spread of the Ebola virus in the 1995 Zaire outbreak. Decontamination is not a priority unless the exposure is acute. Standard precautions are usually sufficient, and special suits (eg, levels A and B) are generally unnecessary.

Whereas the CDC lists six Category A (high threat) agents (anthrax [Bacillus anthracis], botulism [Clostridium botulinum toxin], plague [Yersina pestis], smallpox [variola major], tularemia [Francisella tularensis], and viral hemorrhagic fevers [filoviruses (eg, Ebola, Marburg)] and arenaviruses [eg, Lassa, Machupo]), this chapter focuses on three biologic agents—anthrax, plague, and smallpox—that represent the greatest interest. 7-8

Anthrax

Principles

Bacillus anthracis, a gram-positive spore-forming bacterium, is the causative agent of anthrax (“woolsorter’s disease”). The spores are extremely hardy and can survive for years in the environment. The disease is caused by exposure to the spores, not the bacilli in their vegetative state. It is normally a disease of sheep, cattle, and horses and is rarely seen in developed countries because of animal and human vaccination programs. Disease in humans can occur when spores are inhaled, ingested, or inoculated into the skin. The spores germinate into bacilli inside macrophages. The bacteria then produce disease by releasing toxins (eg, protective antigen, edema factor, and lethal factor) that cause edema and cell death. Russia and the United States have developed anthrax into a biologic weapon. The effectiveness of this agent was clearly demonstrated by two events: an accidental release of spores from a biologic weapons facility in the former Soviet Union town of Sverdlovsk in 1979 and the intentional distribution of anthrax spores through the mail along the eastern seaboard of the United States in 2001. 5

After the Sverdlovsk release, at least 66 people died downwind from the compound during the next several weeks, and animal cases of anthrax were reported 30 miles away. The ability of non–state-sponsored terrorist groups to develop anthrax as a weapon is uncertain. The Japanese organization Aum Shinrikyo made several attempts to disperse anthrax throughout Tokyo without success. The individual believed responsible for the United States anthrax attack was not a foreign national. This is consistent with the fact that the strain of anthrax used in the attack (Ames strain) was developed by the United States government.

Inhalational anthrax is the most lethal form of the disease and is caused by inhalation of spores into the lungs. The mortality rate was thought to exceed 90%. However, data from the 2001 anthrax exposure call this figure into question (5 deaths in 11 cases). Although the actual mortality rate is unknown, and would depend on availability of intensive care resources, it is probably in the 50% range. The minimum number of spores required to produce disease is unknown. The original number quoted in the literature—1000 spores—appears high given the experience following the 2001 anthrax event.

Clinical Features

After phagocytosis by macrophages, the spores germinate and are transported to the tracheobronchial lymph nodes, where the bacteria multiply. During the next 2 to 10 days, patients have an influenza-like illness, with malaise, fever, and nonproductive cough. This initial phase can be delayed for more than 1 month in some patients. Within 24 to 48 hours, abrupt deterioration occurs, with overwhelming sepsis, shock, hemorrhagic mediastinitis, dyspnea, and stridor. A chest radiograph obtained at this time may show a widened mediastinum and hilar adenopathy; but typical radiographic findings are not dramatic and could be missed (Fig. 193.1). Computed tomography (CT) scanning of the

![Fig. 193.1. Chest radiograph of anthrax patient showing diffuse left lung consolidation consistent with pneumonia. There is no mediastinal widening. (Courtesy Centers for Disease Control and Prevention [CDC].)](image)
Chest is more sensitive and should be performed if the disease is suspected. Bloody pleural effusions can also occur, and examination of the lung fields frequently reveals consolidation. This can easily be confused with pneumonia (Fig. 193.2). Death usually results within 3 days, and 50% of patients have hemorrhagic meningitis. Human-to-human transmission has not been reported with inhalational anthrax.

Initial diagnosis is generally made clinically on the basis of an influenza-like or septic illness; a suspicious chest radiograph or CT scan demonstrating hilar adenopathy, infiltrates, or pleural effusions; and a reason to consider anthrax in the first place (eg, current outbreak or warning from authorities). Several clinical algorithms exist that attempt to separate patients with influenza from those with anthrax. As these are based on a handful of anthrax cases, their usefulness remains in doubt. Sputum culture, Gram's stain, and blood cultures are not helpful until late in the course of the disease. Tests to confirm the diagnosis of inhalational anthrax include the polymerase chain reaction for identification of anthrax markers in pleural fluid, serologic detection of immunoglobulin to protective antigen, and immunohistochemical testing of biopsy specimens.

In addition to inhalational anthrax, cutaneous anthrax can occur in any area where large numbers of spores are released, as was the case in the United States in 2001. This form of the disease occurs when spores are introduced into the skin, usually through open wounds or abrasions. The mortality rate is approximately 20% without treatment and 1% with treatment. After an incubation period of 1 to 5 days, a papule develops, progressing to form a large vesicle during the next several days. Severe edema occurs around the lesion and is associated with regional lymphadenitis. Patients then experience severe abdominal pain, hematemesis, ascites, and bloody diarrhea and may present with an acute abdomen.

Management

Traditional treatment of anthrax infection has been penicillin. However, weapons-grade anthrax is probably resistant to penicillin (although this was not the case with the United States attack). Current treatment recommendations reflect this fact (Box 193.5). These consensus recommendations include fluoroquinolones and tetracycline for all children, regardless of age. Balancing the potential risks of such drugs against the consequences of infection by drug-resistant anthrax strains, the benefits justify the recommendations. Nontoxic victims with cutaneous anthrax can be treated as outpatients with oral ciprofloxacin or doxycycline for 7 to 10 days. Doxycycline is equally effective and may be better tolerated (less diarrheal side effects) than ciprofloxacin. Victims with inhalational, cutaneous, or gastrointestinal disease and toxicity require intravenous therapy with ciprofloxacin or doxycycline plus at least one other antibiotic (eg, linezolid, clindamycin, or an aminoglycoside) that inhibits protein synthesis. If meningitis is present, a third antibiotic is added that can penetrate the central nervous system (meropenem). Patients can be switched to oral antibiotics when toxicity resolves. Other modalities that may be helpful include chest tube drainage of pleural effusions, addition of antibody-based therapies (raxibacumab and anthrax immune globulin), and possibly tracheal intubation and mechanical ventilation. Surprisingly, the latter intervention did not improve
Bubonic plague occurs when organisms are inoculated into the skin, usually from a flea bite. During the 2- or 3-day incubation period, the bacilli migrate to regional lymph nodes, where they multiply and cause inflammation and necrosis of lymphatic tissue, resulting in large, tender nodes, or buboes. Typically, buboes develop in the groin, axilla, or cervical region and are so painful that the patient will refrain from moving the affected area (Fig. 193.4). Individuals experience fever, chills, and weakness. In approximately 25% of patients, vesicles or ulcerations occur at the site of inoculation (Fig. 193.4). The mortality approaches 100% if left untreated.

Treatment is to continue for 60 days or until the patient has received three doses of the anthrax vaccine, given on days 0, 14, and 28. The complete vaccine course requires 18 months. This treatment regimen is also recommended for children and pregnant women. If the anthrax strain proves susceptible, patients can be switched to intravenous penicillin or oral amoxicillin. In vitro studies suggest that ofloxacin or levofloxacin can be substituted for ciprofloxacin.

For postexposure prophylaxis, oral ciprofloxacin (500 mg) or doxycycline (100 mg) twice a day is recommended. Amoxicillin can be substituted if sensitive strains are identified. Antibiotic prophylaxis is to continue for 60 days or until patients have received at least three doses of the vaccine. The vaccine is approved by the U.S. Food and Drug Administration (FDA) for adults but not for children. However, it could become available for use in the pediatric population under the Investigational New Drug process if needed. A review by the Institute of Medicine (IOM) found the vaccine both safe and effective for prophylaxis against inhalational anthrax in adults.
site of the flea bite. The buboes are usually nonfluctuant but rarely can suppurate. Organisms can be aspired from the nodes for diagnosis, but incision and drainage are not recommended because the lymphadenitis resolves with antibiotic treatment, and practitioners could become infected if they are exposed during the procedure.

During the next week or more, the bacteria disseminate in approximately 50% of patients with bubonic plague. These victims have septicemic plague or secondary pneumonic plague and die if they are untreated. Those with septicemic plague experience endotoxemia, shock, disseminated intravascular coagulation, and coma. If bacteremia does not occur, most victims recover. A small percentage of those infected by fleas have septicemic plague without detectable buboes. Direct human-to-human transmission does not occur with bubonic or septicemic plague. However, both of these conditions can lead to secondary pneumonic plague, which is communicable. Therefore, initial isolation (for the first 48 hours) is recommended for all patients with plague.

Differential Diagnosis

The preliminary diagnosis of plague is clinical. Few diseases other than plague cause fulminant gram-negative pneumonia associated with hemoptysis in previously healthy individuals. Other diseases cause lymphadenopathy and the differential diagnosis for such conditions includes cat-scratch disease, tularemia, and staphylococcal or streptococcal infections. However, the extremely tender nature of the lymphadenopathy and the toxicity of the patient strongly suggest plague. Once the disease is suspected, Gram's stain and culture of sputum, blood, cerebrospinal fluid, or lymph node aspirate are helpful. State health departments or the CDC can test specimens for the presence of the capsular antigen by direct fluorescent antibody staining. Polymerase chain reaction also holds promise. Because all laboratory tests require several days to complete, initial management decisions are based on clinical findings.

Management

Antibiotic treatment is essentially identical for all three types of plague (Box 193.6). The same caveats for the use of fluoroquinolones and tetracycline in children and anthrax apply to plague. In the case of pneumatic and septicemic plague, treatment should be started within 24 hours of symptoms for outcome to be improved. Antibiotics are given for a minimum of 10 days. As patients improve, oral antibiotics are substituted for intravenous therapy to complete the course. Respiratory isolation of patients with pneumonic plague is necessary for 4 days after beginning of antibiotics to guarantee sterilization of sputum. Patients with septicemic and bubonic plague require isolation for 48 hours. If they do not have pneumonia or draining lesions during this time, isolation can be discontinued. Nonseptic patients with mild bubonic plague can be treated at home with oral doxycycline or tetracycline for 10 days.

The mainstay of prophylaxis against plague remains oral antibiotics. A vaccine exists but has no value in an acute outbreak. It is effective only against bubonic disease and takes several months to impart immunity. The drugs for prophylaxis are tetracycline, doxycycline, ciprofloxacin, chloramphenicol, and possibly trimethoprim-sulfamethoxazole for children.

Smallpox

Principles

Smallpox was eradicated in 1980. The only known repositories of the variola virus, the etiologic agent of smallpox, are in the United States and Russia. However, Russia was successful in weaponizing the virus, which may have been sold or smuggled out of the country. The effectiveness of Russia’s weaponized strain was demonstrated in 1971 when an individual became infected while traveling on a ship 15 km downwind from a Soviet bioweapons test site (Vozrozhdeniy Island in the Aral Sea). Furthermore, in July 2014, several vials of smallpox were discovered in an unused storage room at the National Institutes of Health in Bethesda, MD, raising serious concerns about the security of the virus. In addition, most of the world’s population is no longer fully immune to infection because vaccination against smallpox ceased approximately 40 years ago in nonmilitary personnel. Given its high infectivity and lethality, this makes smallpox an excellent biologic weapon.

The variola virus is spread as an aerosol. It can survive for 24 hours and possibly 48 hours in the environment. The occurrence of smallpox in hospital employees whose only exposure was handling of laundry from infected people is testimony to its viability. Approximately 30% of exposed people become ill. One infected person has the potential to infect up to 20 other individuals. People are infectious from the time the rash first appears until the scabs fall off (1 or 2 weeks). Anyone exposed to smallpox should be closely monitored by public health authorities for 17 days to rule out infection.

Clinical Features

The disease is manifested clinically in several forms. Variola major and variola minor represent 90% of the cases. Variola major is the

- Doxycycline, 2.2 mg/kg bid (maximum 200 mg/day)
- Ciprofloxacin, 20 mg/kg bid (maximum 1 g/day)
- Chloramphenicol, 25 mg/kg qid

**Pregnant Women**

Same as above but exclude chloramphenicol

*Although streptomycin is recommended as first-line treatment, it may not be readily available.

IM, Intramuscular; IV, intravenous.
classic form, a more severe illness with a mortality rate of 30%. Variola minor is a milder form, with less toxicity, fewer pox, and a mortality rate of 1%. Two other forms of the disease, hemorrhagic and malignant (or flat) smallpox, are seen in 10% of cases; the mortality rate is greater than 90%. Patients with hemorrhagic smallpox have symptoms earlier and become toxic quickly. Instead of pox, their rash is characterized by petechiae and hemorrhage. Death occurs in 5 or 6 days. Those with malignant smallpox have a similar course, but their rash is characterized by soft, flattened lesions that do not progress to pustules. If they survive, the lesions resolve without forming scabs.

The infection begins when the virus is inhaled. After migrating to regional lymph nodes, the virus replicates for 3 or 4 days and then asymptomatically spreads to the spleen, bone marrow, other lymphoid tissue, and liver. A second viremia occurs 8 to 12 days later and is associated with fever, prostration, and headache. Mental status changes can occur. During this phase, which lasts 2 or 3 days, the virus localizes to the skin and pharyngeal mucosa. A maculopapular rash soon appears, which becomes vesicular and finally pustular. In contrast to chickenpox, the rash first appears on the face and forearms, later spreading to the legs and trunk. All the lesions in any one area of the body are at the same stage (Fig. 193.5). During the next 8 to 14 days, the pustules crust over and separate from the skin, leaving pitted scars.

A clinical algorithm developed by the CDC can assist in assessing the probability that an individual has smallpox. It relies on three major and five minor criteria. The major criteria are a febrile prodrome, classic smallpox lesions, and lesions in the same stage of development. The minor criteria are centrifugal distribution of pustules; first lesions on the oral mucosa, face, or forearms; toxic appearance; slow evolution of lesions; and pustules on the palms and soles. A patient with all three major criteria is at high risk and should be isolated and reported to public health authorities and law enforcement agencies as soon as possible. Patients with the febrile prodrome and either four minor criteria or one other major criterion are at moderate risk. Emergency clinicians should consult with infectious disease and dermatology specialists and order tests to confirm varicella. If smallpox cannot be ruled out after these interventions, the patient should be treated as high risk. If a patient does not have the febrile prodrome or has the prodrome but no other major criteria and has fewer than four minor criteria, the individual is at low risk for smallpox. These patients can be managed as clinically indicated.

Differential Diagnosis

As with anthrax and plague, the initial diagnosis of smallpox is clinical. Other illnesses resembling smallpox include chickenpox, herpes simplex, and monkeypox. Unlike with variola, the rash associated with chickenpox (varicella) is seen first on the trunk and then spreads to the extremities and face. In addition, the pustules are in different stages of evolution in any one area of the body. If the first case seen is hemorrhagic or malignant smallpox, the diagnosis will probably be missed until more typical cases present.

Diagnostic Testing

For confirmation of the diagnosis, vesicular fluid or scabs are sent for electron microscopic examination or tissue culture. Polymerase chain reaction techniques are also useful for rapid viral identification, with sensitivities and specificities in the 98% range.

Management

No effective therapy exists for victims infected with smallpox who become symptomatic. However, potential antiviral agents, such as tecovirimat and cidofovir, show promise. In mice exposed to a lethal cowpox challenge, administration of an oral lipid prodrug of cidofovir in modest doses once a day for 5 days produced 100% survival. Vaccinia immune globulin (VIG) has no role in the treatment of active disease. Some practitioners suggest that most smallpox patients should be isolated at home or other nonhospital facilities because the virus spreads easily in a hospital environment and the disease is currently untreatable.

The best strategy for containment of the disease is vaccination of the susceptible population. Vaccination of an immunocompetent individual within 3 days of exposure will prevent or significantly ameliorate illness. Vaccination up to 7 days after exposure may prevent death. Complications from vaccination with vaccinia virus occur and can be fatal. Groups at risk for these adverse consequences include pregnant women and people with eczema, human immunodeficiency virus (HIV) infection, and immunosuppressive conditions (eg, malignant disease, chronic steroid use, and hereditary immunodeficiencies). Given the seriousness of the disease, the current recommendation is to vaccinate these individuals if there is risk of exposure and simultaneously administer 0.3 mL/kg of VIG intramuscularly. For people who have complications from the vaccine (eg, progressive vaccinia, ocular autoinoculation, and eczema vaccinatum), the dose of VIG is 0.6 mL/kg intramuscularly and is divided during 24 to 36 hours. Ribavirin can be administered but is considered experimental. VIG is not indicated for vaccinia-associated encephalitis.

The smallpox vaccine supply situation has improved dramatically in the United States. The CDC has replaced the traditional smallpox vaccine (Dryvax) with a next generation product, ACAM2000, in sufficient quantity to immunize the United States population. A British company developed the second-generation vaccine from the same vaccinia virus used in Dryvax but grown in cell cultures. As a consequence, its use can still produce the same adverse reactions as Dryvax. To improve the vaccine’s safety profile, work has commenced on production of an improved vaccine based on a different vaccinia strain. Two new candidate vaccines, LC16 and Modified Vaccinia Ankara, show promise. Preliminary studies demonstrate safety and immunogenicity in populations for whom the traditional vaccine is contraindicated. The virus used in the modified vaccinia Ankara vaccine is so attenuated that it does not replicate in a human host. This may make it safe for administration to immunocompromised individuals.

**CHEMICAL WEAPONS**

Unlike victims of biologic weapons, casualties exposed to chemical agents manifest symptoms quickly, from acutely to a few hours after chemical contact. Therefore, surveillance and recognition
are less problematic. The challenge is decontamination and treatment. Terrorism with chemical weapons produces casualties similar to those seen in hazardous materials incidents, and medical management is comparable. However, the unique features of such events, including the volume of patients and the risk of hospital contamination, necessitate additional preparation. For example, the Tokyo subway attack with use of sarin in 1995 resulted in 11 deaths and more than 5000 patients converging on local EDs. Although the majority of these patients had subclinical exposure or psychological symptoms alone, the health care system was severely stressed. Secondary contamination by direct contact or vaporization occurred in ambulances and at the hospitals.

Health care facilities should have protocols in place to deal with the eventuality of chemically contaminated patients (Box 193.7). Current recommendations for levels of PPE and types of decontamination facilities necessary in a hospital setting have been advanced, but evidence-based recommendations remain inconclusive. Collection of waste water from the decontamination process in a containment vessel is ideal but not required if this would impede necessary and appropriate actions to protect human life (https://nepis.epa.gov/Exe/ZyNET.exe/P1002ZKP.txt).

The four basic classes of chemical compounds are nerve agents, vesicants (blistering), cyanides (previously referred to as choking agents), and pulmonary intoxicated (previously referred to as choking agents). Although all have potential for use as weapons, the nerve agents and vesicants are thought to represent the greatest threat.

**Nerve Agents (Sarin, Tabun, Soman, and VX)**

**Principles**

Nerve agents are organophosphates. They inhibit the enzyme acetylcholinesterase, blocking the degradation of acetylcholine at the postsynaptic membrane. Acetylcholine accumulates, resulting in overstimulation of muscarinic and nicotinic receptors.

**Clinical Features**

Symptoms are receptor dependent. Stimulation of muscarinic receptors produces miosis, salivation, rhinorrhea, lacrimation, bronchorrhea, bronchospasm, vomiting, and defecation. The major life threat associated with this syndrome is ventilatory compromise from profound bronchorrhea and bronchoconstriction. Stimulation of nicotinic receptors produces muscle fasciculations, flaccid paralysis, tachycardia, and hypertension. Unlike with typical organophosphates, exposure to nerve agents has not been associated with urination, although bradycardia is rare, and miosis does not respond to systemic therapy.

Nerve agents also cause direct central nervous system toxicity that is manifested as seizures, coma, and apnea. In survivors, residual central nervous system effects are manifested as psychological changes that can last 4 to 6 weeks. These manifestations are caused by chemical effects, not stress.

A preliminary diagnosis of nerve agent exposure is based on clinical findings. Important features include muscle fasciculations and miosis, which are sufficient to justify treatment pending further evaluation. Diagnosis is confirmed by measurement of red blood cell cholinesterase levels. This test may not be readily available, and results are difficult to interpret without a baseline level as significant variation exists within normal populations. Therefore, treatment is to begin before test results are known.

Terrorists are most likely to use the nerve agents sarin (designated GB) and VX. Sarin exists as a liquid at room temperature but represents primarily a vapor threat because of its high volatility. Symptoms occur within seconds after inhalation of vapor and peak at 5 minutes. There are no delayed effects; patients remaining asymptomatic 1 hour after possible chemical contact have not received a clinically significant exposure. They can be sent home. VX is a thick liquid with low volatility. It represents a liquid threat only. In general, patients have symptoms after skin exposure. The median lethal dose (LD₅₀) for VX is 10 mg, a droplet slightly larger than a pinhead. Death from doses of this size occurs in less than 30 minutes. Delayed symptoms occur, so individuals should be observed for 18 hours before potential intoxication can be ruled out.

**Management**

Decontamination of victims exposed to sarin vapor requires removal of clothing. People contaminated with VX or liquid sarin should have their clothing removed and then be decontaminated using showers. When the level of exposure or the involved agent is uncertain, full decontamination is prudent. Responders caring for patients in the presence of liquid sarin exposure may require level A or B protective suits.

The treatment of nerve agent victims depends on the form (liquid or vapor) and level of exposure (mild, moderate, or severe) (Box 193.8). Three drugs are the mainstay of treatment: atropine for the muscarinic effects (improves ventilation), pralidoxime chloride (2-PAM) for the nicotinic effects (reverses paralysis), and diazepam for the prevention and treatment of seizures (Box 193.9). The dose of atropine is titrated to the drying of respiratory secretions and not to heart rate or pupil size. 2-PAM is most effective if it is administered within 4 to 6 hours of sarin exposure. After this period, the drug’s impact wanes because of “aging.”
Treatment of Nerve Agent Exposure*

**VAPOUR**
- Mild: Observe for 1 hour, then release; no treatment
- Moderate: One or two Mark I kits IM; or atropine, 2 to 4 mg IV, may repeat every 5 to 10 minutes as needed; and 2-PAM, 1 g IV during 30 minutes, may repeat every hour as needed
- Severe: Three Mark I kits IM and one diazepam autoinjector IM; or atropine, 6 mg IV, may repeat 2-mg boluses IV every 5 to 10 minutes; and 2-PAM, 1 g IV during 30 minutes, repeat every hour for total of 3 g; and midazolam or diazepam, 5 mg IV, or midazolam 10 mg IM, may repeat as needed

**LIQUID**
- Mild: One Mark I kit IM; or atropine, 2 mg IV; and 2-PAM, 1 g IV during 30 minutes
- Moderate: Same as for vapor
- Severe: Same as for vapor

**PEDIATRIC DOSES**
- Atropine, 0.02 mg/kg IV
- 2-PAM, 20 to 40 mg/kg IV during 20 to 30 minutes
- Midazolam, 0.15 mg/kg IV; or diazepam, 0.2 to 0.3 mg/kg IV

*Give atropine before attempting intubation. Otherwise, airway resistance will inhibit ventilation. Continue atropine until secretions are dry (usually 20 mg). In hypoxic patients, IV atropine has been reported to cause ventricular fibrillation, so consider use of IM atropine.

IM, Intramuscular; IV, intravenous.

---

**Vesicants (Mustard)**

**Principles**

Vesicants (blistering agents) are chemical warfare agents that induce blister formation on contact with skin. Terrorists could use several of these compounds, but sulfur mustard is considered the most likely. Mustard is a liquid at room temperature but has both liquid and vapor toxicity. Injury from mustard exposure occurs in 1 or 2 minutes, but symptoms do not develop for 4 to 8 hours.

**Clinical Features**

The exact mechanism is unknown, but the agent damages DNA, causing eventual cell death. These effects are similar to radiation exposure and often described as “radiomimetic.” Mustard has both local and systemic toxicity. Local effects occur from direct exposure to the skin, eyes, and airway. Systemic effects result from the impact of absorbed mustard on the bone marrow.

**Management**

Treatment is supportive and includes decontamination (to prevent secondary contamination) and airway maintenance. No specific antidote for mustard is currently available. A topical iodine preparation showed promise in initial trials but did not demonstrate efficacy in larger studies.

Eye damage from mustard exposure varies from conjunctivitis to corneal ulcer and perforation; however, only 1% of patients have permanent eye damage. Ninety percent of ocular injuries will heal within 2 weeks to 2 months of exposure without sequelae. Severe pain is frequently associated with mustard injury and causes significant blepharospasm. Irrigation is beneficial if it is performed within minutes of exposure but ineffective once symptoms occur. Standard treatment includes mydriatics, topical antibiotics, oral analgesics, and petroleum jelly applied to the lids to prevent adhesions. Commercially available topical antibiotic/glucocorticoid ophthalmologic ointments have demonstrated efficacy when applied early in animal models. Application of this drug combination in the first few hours to days of exposure appears to reduce inflammation and subsequent injury. Continued use of topical steroids should occur under the supervision of an ophthalmologist.

The hallmark of mustard injury is skin blisters resembling second-degree burns. Within 4 to 8 hours of exposure, erythema and burning occur, followed by vesicle and bulla formation. Most vapor injuries do not involve the entire dermis, so wounds will not require skin grafting. If liquid exposure occurs to skin, full-thickness burns may result. The patient should be decontaminated by removal of clothing and washing with water or a dilute bleach (1:10 hypochlorite) solution. More concentrated bleach solutions are contraindicated, because they can cause skin damage. Decontamination immediately after exposure, ideally at the scene, prevents further injury to the patient, but delayed decontamination is indicated to protect staff. Treatment is supportive and includes standard burn wound management, analgesia, and tetanus prophylaxis. An important exception is fluid resuscitation. Fluid losses from mustard injury are much less than those associated with thermal burns. Therefore, standard burn formulas for fluid administration do not apply, and caution should be used to avoid overhydration.

The degree of airway injury after mustard exposure is dose dependent. Mild exposure causes irritation of the nose, sinuses, and pharynx and can be treated with cool, humidified mist. Moderate exposure extends to the larynx and upper trachea and may require treatment with oxygen, continuous positive airway pressure, or even intubation. Severe exposure involves the lungs, producing hemorrhagic necrosis of the bronchioles. Pulmonary edema is rare. Intubation is usually required, and patients may benefit from positive end-expiratory pressure and inline bronchodilators. Steroids are of questionable benefit, and antibiotics should be given only for established infection. Recent trials of inhaled tissue plasminogen activator in a rat model of sulfur mustard pulmonary injury show promise.
Systemic toxicity from mustard is caused by bone marrow suppression. Absorbed mustard kills stem cells, causing the white blood cell count to decline after 3 to 5 days. Survival is rare if the white blood cell count falls below 200, which generally occurs when more than 50% of the total body surface area is involved from exposure to liquid agent. Death after mustard exposure usually results from secondary infection and respiratory failure.

Cyanides (Blood Agents)

Principles
Cyanide molecules, most typically hydrogen cyanide or cyanogen chloride, bind to cytochromes within mitochondria and inhibit cellular oxygen use.

Clinical Features
Low-dose exposures result in tachypnea, headache, dizziness, vomiting, and anxiety. Symptoms subside when the patient is removed from the source. At higher doses, the symptoms progress to seizures, respiratory arrest, and asystole within minutes of exposure.

Management
Victims should be removed from the area, have their clothing discarded, and receive oxygen. If no improvement occurs, the cyanide antidote is given. This has traditionally been the sequential administration of amyl nitrate, sodium nitrite, and sodium thiosulfate. However, the FDA has approved intravenous hydroxocobalamin for treatment of cyanide exposure. The initial dose is 5 g and can be repeated if necessary.\textsuperscript{13-15}

Pulmonary Intoxicants (Phosgene and Chlorine)
Pulmonary or choking agents cause an inflammatory reaction when they come into direct contact with the eyes and upper airway. They can be life-threatening if inhaled. No specific antidote exists. Treatment is mainly supportive and consists of removal of the patient from the source, decontamination, airway maintenance, bronchodilator administration, and eye irrigation.

CHAPTER 193: QUESTIONS & ANSWERS

193.1. Three patients arrive at triage simultaneously: One has received a 4 Gray work-related irradiation exposure from a food sterilizer but no other injury, one is experiencing an acute ST elevation myocardial infarction (MI), and one likely has urosepsis but with a stable blood pressure and heart rate of 105 beats/min. Which of these patients should receive your attention first?

A. Activate the cardiac catheterization team.
B. Decontaminate the irradiated victim before placing him in a room.
C. Initiate intravenous (IV) fluid bolus and prepare for intubation of the radiation-exposed patient.
D. Place a central venous catheter in the urosepsis patient.
E. Place the irradiated victim in an isolation room.

Answer: A. Even patients who have received a lethal radiation dose do not die quickly as a consequence of the ionizing exposure. Patients should still be triaged according to severity of the medical conditions and/or vital sign derangements. Here, the patient with the MI is most acute and should be treated first by activating the cardiac catheterization team. The radiation-exposed patient was not contaminated, just irradiated. As such, decontamination and isolation are not necessary. Although the victim has received the LD50/30 dose of ionizing radiation, no significant injury will result just after exposure, so this patient does not take priority over the MI patient at this point and intubation is not indicated. The septic patient is not critically ill and should not be treated ahead of the MI patient.

193.2. Which of the following statements best describes issues in management of anthrax infection?

A. Antibiotics do not change the mortality of cutaneous disease.
B. Cutaneous anthrax lesions are not tender.
C. Doxycycline or ciprofloxacin is the single-agent treatment for symptomatic inhalational anthrax.
D. Intubation/mechanical ventilation clearly improves mortality from inhalational anthrax.
E. Sputum culture and Gram’s stain obtained early in the disease help differentiate inhalational anthrax.

Answer: B. Cutaneous anthrax causes a severe, although non-tender, peripheral vesicle and then eschar with regional adenopathy. Antibiotics lower the mortality from cutaneous anthrax twentyfold. For inhalational, gastrointestinal, and cutaneous anthrax with toxicity, intravenous (IV) treatment is with ciprofloxacin or doxycycline plus at least two other agents. Regarding inhalational anthrax, mechanical ventilation may not improve mortality, and sputum cultures and Gram’s stains are not helpful until late in the disease.

193.3. Several children ages 5 to 8 years old have definitely been exposed to anthrax spores. Health department officials have brought these children to the emergency department (ED). They are all ambulatory with normal vital signs and without symptoms. Which of the following is the most appropriate management?

A. Admission for parenteral penicillin G
B. Doxycycline for 5 days
C. Observation
D. Outpatient ciprofloxacin for 60 days or until the children have received three doses of vaccine
E. Penicillin VK for 7 to 10 days

Answer: D. See Box 193.5. For children without toxicity, ciprofloxacin, doxycycline, or amoxicillin orally is indicated for a minimum of 60 days or until the child has received three doses of vaccine. The vaccine has not been approved for children but may be indicated to reduce the long-term exposure to antibiotics. Note that weaponized anthrax may be penicillin resistant.

193.4. An individual is exposed to sarin vapor. She presents complaining of difficulty with vision, salivation, vomiting, and the urge to defecate. The most appropriate treatment for this patient is which of the following?

A. 5 mg diazepam intravenous (IV)
B. 6 mg atropine IV and 1 g 2-PAM IV every hour for a total dose of 3 g
C. 10 mg diazepam intramuscular (IM) via auto-injector
D. Observation for 6 hours and then discharge if she does not develop new symptoms
E. One or two Mark 1 kits IM

Answer: E. The victim described would be characterized as a moderate exposure to sarin vapor. As such, treatment is indicated with one or two Mark 1 auto-injectors IM. Observation would not be appropriate. Diazepam is not indicated for moderate exposures. If an IV is established, the initial treatment is atropine 2 to 4 mg IV and 2-PAM 1 g IV.

**KEY CONCEPTS**

- Knowledge of wound mechanics and production, as well as wound appearance, can provide practicing emergency clinicians with important clues regarding the forensic interpretations of injuries.
- Wounds and injuries should be diagrammed and photographed.
- The medical record should accurately document objective findings associated with a patient’s wounds. Emergency clinicians should not speculate about their mechanism or cause.
- Any evidence collected during the course of treatment must be documented in the medical record, including to whom the evidence was given, for the chain of custody to be preserved.
Clinical forensic emergency medicine is the application of forensic medical knowledge, techniques, and procedures to the management of live patients in the emergency department (ED). It is a key link through which patients or victims of violence can receive recourse for the actions against them. Emergency clinicians are in the unique position of being the first contact for most of these patients and play a crucial role in this process. They are also the clinicians who have the most contact with law enforcement, and are therefore well suited to aid in evidence conservation. However, many emergency clinicians have limited training in clinical forensic emergency medicine and, as such, critical information or data can be missed during these interactions.

All patients who are victims of physical or sexual assault, abuse, or trauma have forensic needs. When treating injuries without consideration of their forensic significance, emergency clinicians may misinterpret wounds, fail to recognize victims of abuse or domestic violence, and inadequately describe the physical appearance of the wounds. During the provision of patient care, evidence that can be of critical significance to criminal or civil proceedings can be lost, discarded, or inadvertently washed away, despite requirements by The Joint Commission to “preserve evidentiary materials and support future legal actions.” Prior studies have shown that evidence may be accidentally discarded during the initial evaluation and that injuries are also improperly documented.

Emergency medicine programs have identified and described the need for forensic training in their residency curricula. The American College of Emergency Physicians established the Forensic Medicine Section in 2006 to provide emergency clinicians with additional forensic resources and training. Unfortunately, however, no formal training programs currently exist. In contrast, the British Royal College of Physicians established the Faculty of Forensic and Legal Medicine (FFLM) in 2006 as the authoritative body on clinical forensic medicine in the United Kingdom. The FFLM has created training and certification programs and board-type certification examinations after 2 years of forensic practice for British physicians.

There are a number of important ways to address this gap through training and exposure to clinical forensic emergency medicine. Forensic examinations should be conducted with the consent of the patient, legal guardian, or court or by implied consent. The evaluation should include a history and physical examination in which all wounds are documented and described in as much detail as possible, as well as photographs and anatomic diagrams. Even simple findings, such as contusions or ecchymoses with associated injuries may serve as important clues as to how the injury was sustained and may be invaluable in future legal proceedings. Evaluations of gunshot and stab wounds, physical or sexual abuse, domestic violence, and motor vehicle–related trauma should also be adequately documented for possible use as evidence. Documentation should include digital photographs as well as a narrative and diagrams.

Evidentiary material, such as clothing, bullets, and shrapnel, should be collected. Clothing should be stored in a paper bag; bullets and other metallic foreign bodies should be handled minimally and with gloved hands. Contact with metal instruments should also be avoided because these can alter the markings present.

When physical injuries are misinterpreted, and these misinterpretations are entered into the medical record, or when valuable evidence is lost or destroyed in the process of providing patient care, there are consequences for the legal proceedings that may follow. These acts of omission or commission may deny patients their deserved redress in the justice system. To protect the interests of patients, EDs should implement protocols for wound documentation and evidence collection. A proper understanding of the forensic relevance of certain observations is the key to protecting the rights of victims of assault.

**FORENSIC ASPECTS OF GUNSHOT WOUNDS**

**Background**

**Ballistics**

Ballistics is the science of the motion of projectiles in flight. In relation to firearms, it is the study of the interaction of a bullet (or missile) from when it leaves the gun cartridge until it makes contact with tissue. Ballistic physics is broken down into three parts, based on the material with which the bullet interacts:

1. *Internal ballistics,* which pertains to the projectile while in the firearm
2. *External ballistics,* or the path of the projectile from when it leaves the firearm until it reaches the target
3. *Terminal (or wound) ballistics* 

**Internal ballistics** factors in the design of the firearm and how the combustion of gunpowder within the firearm generates the pressure that subsequently projects the missile. External ballistics takes into consideration the effects of gravity and drag on the missile and how that affects the distance travelled and the accuracy with which it hits the intended target.

Wound ballistics is the most clinically relevant because it is the study of the effects of penetrating projectiles on the body. Tissue disruption (wound severity) is directly related to the amount of kinetic energy (\(KE = \frac{1}{2}mv^2\)) transferred to it, not to the total amount of kinetic energy possessed by the bullet. There are two broad categories of weapons based on the amount of potential kinetic energy that can be transferred from the missile to the tissue:

1. *High-velocity weapons,* which generate velocities from 1500 to 4000 ft/s (or >600 m/s). Examples of these are rifles or military weapons. Consequently, bullets fired from such weapons possess a higher kinetic energy and, therefore, theoretically have a greater wounding capacity.
2. *Low-velocity weapons,* which generate velocities ranging from 700 to 1600 ft/s (or <600 m/s). These weapons include handguns and air rifles (BB guns).

Rifle bullets have more kinetic energy and a theoretically higher wounding potential, but energy transfer (and, by extension, wound severity) is the result of multiple variables. The most
are bullet type (eg, weight, deforming type, fragmenting type), bullet velocity, and the characteristics, location, and nature of the impacted tissue itself (tissue over bone or tissue over organs). Interestingly, high-velocity bullets tend to travel straight through tissue, with minimal energy dissipation. The formula $KE = \frac{1}{2}mv^2$ better reflects the actual energy transfer occurring during tissue penetration and wounding.11

The principal mechanism for tissue damage by bullets is crushing. A bullet traveling through tissue generates two cavities, one permanent and the other temporary. The size of the permanent cavity varies with the size, shape, and configuration of the bullet. A hollow point bullet that mushrooms can increase its diameter 2.5 times on impact and will increase the area of tissue crush 6.25 times compared with a nondeformed bullet. The temporary cavity results from a shock wave generated as the bullet enters the tissue, which results in a brief distortion or stretching of the tissue.7,10 This tissue distortion lasts for a brief amount of time, 5 to 10 milliseconds from its generation until its collapse, and leaves behind the permanently crushed tissue and permanent cavity.7,8,10 The effect of the temporary cavity depends on the elasticity of the tissue traversed: solid organs such as the liver, bone, or kidneys do not tolerate this temporary deformation as well as more elastic tissue (eg, lungs, skeletal muscle, skin), and therefore sustain more damage.7 Secondary wounding can occur in situations in which the bullet hits a target (usually bone) and fragments disperse, resulting in further tissue damage.7

Forensic Evaluation of Handgun Injuries

The Weapon. Handguns are the most common firearm available. There are four categories of handguns: (1) the single-shot weapon (usually a target pistol); (2) the derringer (a small, concealable weapon, usually with two barrels); (3) the revolver (a weapon with a rotating cylinder that advances with the pull of the trigger); and (4) the semiautomatic pistol (which fires with each pull of the trigger). The semiautomatic handgun is the most popular because its magazine, or clip, can hold up to 17 cartridges, whereas revolvers hold five or six cartridges.

Handgun Ammunition. The cartridge, or round, is composed of the primer, cartridge case, powder, and bullet (Fig. e1.1). The bullet is the projectile that is propelled out of the muzzle. The primer is a small explosive charge in the base of the cartridge that ignites the gunpowder. The primer may contain lead, barium, or antimony. These materials may be deposited on the hands of the shooter, on the victim of a close-range assault, or on objects within a room in which the weapon was discharged.

The cartridge case is typically made of brass, although other materials may be used. The function of the cartridge case is to expand slightly, sealing the chamber against the escaping gases and propelling the bullet down the barrel. On detonation, a cartridge case is imprinted with unique microscopic marks that are valuable evidence and should be preserved for law enforcement.

The gunpowder found in all commercial cartridges except blanks is smokeless powder made with a single base (nitrocellulose) or a double base (nitrocellulose and nitroglycerin). When a weapon is discharged, not all the gunpowder is consumed. A percentage of the unburned or partially burned gunpowder will travel out of the end of the muzzle for a short distance (<48 inches). The distance depends on the physical characteristics and shape of the powder and the weapon’s barrel length.

Blank cartridges, muzzleloaders, and other antiques or replicas may use black powder. Black powder—a combination of potassium nitrate, charcoal, and sulfur—does not burn as efficiently as the smokeless powder and results in a large flame and white smoke. It is black powder that produces powder burns by igniting clothing.

The bullet is the projectile that is propelled down the gun barrel at velocities ranging from 700 to 1600 ft/s. The higher velocities are achieved by the inclusion of supplemental gunpowder in the cartridge case (a magnum load; hence, a .357 magnum). The diameter of the bullet’s base is termed its caliber. Bullet caliber is described in hundredths of an inch or millimeters. Handgun bullets range from .22 caliber, or 5.56 mm, to .45 caliber, or 11.3 mm. A bullet’s weight is measured in grains, with 7000 grains/lb.

The most common bullet types are the round nose, full metal jacket, hollow point, wad cutter, and semi-wad cutter. Bullets generally are a solid core of lead or steel. If a jacket covers the bullet core, the jacket’s material is usually copper or aluminum. If the jacket covers only a portion of the core, the bullet is said to be semijacketed. If the jacket is completely covered, it is said to have a full metal jacket. Some bullets have a hole in the tip and are called hollow points. The hole causes the bullet to expand on contact, which significantly increases the damage to tissue.

Forensic Aspects of Rifles

Rifles are shoulder-fired weapons designed to generate significant pressures in the muzzle and, as such, result in firing of ammunition at high speeds.7 Centerfire rifle bullets, .223 to .308 caliber, are similar in diameter to handgun ammunition but, based on the formula for kinetic energy ($KE = \frac{1}{2}mv^2$), their wounding potential is greatly enhanced by the higher velocity of the round. Injuries result from the transference of energy from the projectile to tissue, organs, and bony structures. With medium-velocity rounds (2000–3000 ft/s) and high-velocity rounds (>3000 ft/s), a temporary cavity is formed along the wound tract, which may be 11 or 12 times the diameter of the bullet. High-velocity rounds can also cause tissue damage away from the physical tract taken by the projectile. Because of the amount of energy possessed and transferred to underlying tissue, exit wounds associated with centerfire rifles, in contrast to those associated with handguns, are generally larger than their corresponding entrance wounds (Fig. e1.2).

Forensic Aspects of Shotguns

Shotguns are similar to rifles, but the missiles are multiple small projectiles, all of which have the potential to cause severe injury.7 Shotguns have the barrel length of rifles but can discharge pellets or single slugs down a smooth bore barrel. The caliber of a shotgun...
Forensic Aspects of Air Rifles

Air rifles work very similarly to traditional firearms and generate comparable muzzle velocities as low-velocity weapons. As such, they possess enough kinetic energy to cause severe injuries because they can penetrate tissue, and particularly because they are often fired at close range.

Epidemiology

According to data from the Centers of Disease Control and Prevention, there were 921,163 firearm injuries from 2001 to 2013; firearms accounted for 31,672 fatalities in 2010 alone and represent the second leading cause of injury-related deaths in the United States after motor vehicle trauma. Many studies have suggested that the number of firearm injuries have stabilized in recent years, but a few recent studies have noted a decline in the number of firearm injuries while the mortality rate has largely remained unchanged.

Firearm injuries occur predominantly in males between the ages of 15 and 45 years old, particularly in those of African American ethnicity. Suicides are more common than homicides, and the incidence of the latter appears to be decreasing. Suicides accounted for 60.5% of all firearm fatalities from 2002 to 2012. In a recent study, firearm homicide was the leading cause of death in African American males from aged 15 to 34 years in 2012 and was the second leading cause of death for whites or Hispanic males of the same age range. Firearm violence was the second leading cause of death in females aged 15 to 24 years. In contrast, suicide rates were higher in white males, and the divergence increased with age, starting in adolescence. Hospitalizations for nonfatal firearm injuries have followed the same trend. Stray bullet injuries are also important because they frequently affect females, children, or older adults, who may not have any relation to the associated violence.

Firearm injuries are not limited to adults. Firearm homicide is a leading cause of death in African American youth aged 14 to 24 years old, particularly in those of African American ethnicity. Suicides are more common than homicides, and the incidence of the latter appears to be decreasing. Suicides accounted for 60.5% of all firearm fatalities from 2002 to 2012. In a recent study, firearm homicide was the leading cause of death in African American males from aged 15 to 34 years in 2012 and was the second leading cause of death for whites or Hispanic males of the same age range. Firearm violence was the second leading cause of death in females aged 15 to 24 years. years and the second leading cause of death in other youth, regardless of age or race. Over 15,500 children aged 20 years and younger were treated for nonfatal firearm injuries in the United States in 2010, with 703 firearm unintentional fatalities in children aged 14 years and younger from 2000 to 2010. Adolescents aged 15 to 19 had a nonfatal firearm injury rate three times that of the general population. The medical impact is significant. One recent study noted that there were an estimated 322,730,927 emergency and outpatient visits for children and adolescents aged 1 to 19 years between 2001 and 2010, with an average incidence of 19,897 firearm injuries/year. These patients were more likely to be male, aged 12 to 19 years, African American, and uninsured.

Air rifles also contribute to the prevalence of firearm injuries. About 14,000 shootings occur annually, predominantly in males and in those younger than 19 years, with the highest incidence in children between the ages of 10 and 14 years. Therefore, it is critical to understand and be well versed in the management of such injuries.

To manage patients with firearm-related injuries properly, it is also important to have a thorough understanding of the pathophysiology involved. Several misconceptions exist in the management of these injuries, such as a poor understanding of wound sterility following gunshot injuries, the need for wound débride ment, and the necessity for prophylactic antibiotics. A study published in 2015 showed that such misconceptions were prevalent and were not influenced by prior Advanced Trauma Life Support (ATLS) training. As such, focused training in forensic medicine is necessary to improve knowledge and the ability to treat these patients adequately.

Clinical Features

Errors of Interpretation and Terminology

The emergency clinician is in the ideal position to evaluate and document the state of a gunshot wound because he or she sees and explores it before it is disturbed, distorted, or destroyed by surgical intervention. Documentation of gunshot wounds should include the anatomic location of the wound as well as its size, shape, and distinguishing characteristics, and digital photographs of the wound should be taken. Wounds should be described according to the standard anatomic position, with the arms to the sides and palms facing forward.

Emergency clinicians should not describe wounds as “entrance” or “exit” but, using appropriate forensic terminology, should document a detailed description of the wound, including its appearance, characteristics, and location, without attempting to interpret the wound type or bullet caliber. Exit wounds are not always larger than entrance wounds, and wound size does not consistently correspond to bullet caliber.

The size of any wound (entrance or exit) is determined by five factors—the size, shape, configuration, or angle and velocity of the projectile at the instant of impact with tissue and the physical characteristics of the impacted tissue itself. If the projectile is slowed and its shape unchanged on exiting the skin, the exit wound may be the same size as or smaller than the corresponding entrance wound. If the projectile increases its surface area by fragmenting or changing its configuration while maintaining a substantial velocity, the exit wound may be significantly larger than the entrance wound. If the bullet strikes bone, fragments may extrude from the exit wound and contribute to the size and shape of the wound. Tissue elasticity also affects wound size so that entrance or exit wounds may be smaller, equal to, or larger than the projectile that caused them. Wounds on the palm or sole may appear as slits and can be easily mistaken for stab wounds.

A treating emergency clinician may be requested to render factual testimony, expert testimony, or both in a criminal case. Expert forensic testimony rendered without an appropriate forensic examination or adequate forensic training may mislead participants in the criminal justice system (eg, “the exit wound is always larger than the entrance wound”). Opinions related to entrance versus exit wounds or the range of fire can affect the determination of innocence or guilt.

The subsequent sections highlight the clinical features of entrance and exit wounds that result from the use of different types of firearms. This information is provided to make emergency clinicians aware of the varying presentations, depending on the distance from the target. Again, however, they should refrain from speculating on the type of wound and simply document the findings noted on examination.

Handgun Entrance Wounds

Range of fire is the distance from the muzzle to the victim and can be divided into four general categories: contact, near-contact or close range, intermediate or medium range, and indeterminate or distant range (Table e1.1). The size of the entrance wound does not correlate with the caliber of the bullet because the entrance wounds over elastic tissue will contract around the tissue defect and have a diameter much less than the caliber of the bullet.

Contact Wounds. There are three subcategories of contact wounds: (1) tight contact, in which the muzzle is pushed hard against the skin; (2) loose contact, in which the muzzle is incompletely or loosely held against the skin; and (3) contact through clothing.

In a tight contact wound, all material—the bullet, gases, soot, the incompletely burned pieces of gunpowder, and metal fragments—is driven into the wound. These wounds can vary from a small hole with seared blackened edges from the discharge of hot gases and an actual flame to a gaping stellate wound (Fig. e1.4). Large wounds occur when the wound is inflicted over thin, inelastic, or bony tissue, and the injected hot gases cause the skin to expand until it stretches and tears. These tears will have a triangular shape, with the base of the triangle overlying the entrance wound. Tears are generally associated with .32 caliber or greater, or with magnum loads. Large stellate contact wounds are easily misinterpreted as exit wounds if the determination is based solely on their size (see Fig. e1.4B). Stellate tears are not pathognomonic for contact wounds, however. Tangential wounds, ricochet or tumbling bullets, and some exit wounds may also be stellate. These wounds’ appearance differs from that of tight contact wounds by the absence of soot.

and powder within the wound and a lack of seared wound margins.

In some tight contact wounds, expanding skin is forced back against the muzzle of the gun, leaving a characteristic muzzle abrasion or muzzle contusion (Fig. e1.5). Patterns such as these should be documented before wound débridement or surgery because they are helpful in determining the type of weapon used (revolver vs. semiautomatic).

When a gun’s muzzle or barrel is in loose contact with or is angled to the skin, the soot and gunpowder residues are present within and surrounding the wound. The angle between the muzzle and skin determines the soot pattern. A tangential, loose, or near-contact wound produces an elongated searing and soot deposit surrounding the wound.

Discharge of a weapon in contact with clothing results in the gases and soot being deposited between the garment and skin. This results in a diffuse pattern of soot surrounding a wound, with seared margins (see Fig. e1.4C).

Close-Range Wounds. Close range is the maximum range at which soot is deposited on the wound or clothing. The muzzle to target distance is usually less than 6 inches but may be as much as 12 inches. Beyond 6 inches, most of the soot usually falls away

**Fig. e1.4.** A, Tight-contact entrance wound from a .38-caliber revolver. The wound margins are seared from the discharge of hot gases and an actual flame from the end of the barrel. The triangular tear is the result of tissue expansion from the discharge of gases into the tissue. B, Tight-contact entrance wound with large stellate tears from a .380 semiautomatic pistol. The large triangular tears are the result of rapid expansion of gases under the skin. C, Tangential-contact wound from a 9-mm pistol on the medial aspect of the left calf. The presence of soot at the superior aspect indicates a close range of fire. The patient initially reported that he was shot from a distance of 3 or 4 feet and later admitted that he had accidentally shot himself while withdrawing his pistol from his boot. Large wounds, as seen in B and C, may be misinterpreted as exit wounds because of their size.

**Fig. e1.5.** A muzzle contusion is a contusion caused by skin expansion against the barrel of the weapon. Muzzle contusions are associated with contact wounds.
and does not reach the skin or clothing. The concentration of the soot varies inversely with the muzzle to target distance and is influenced by the type of gunpowder and ammunition used, length of the weapon's barrel, and caliber and type of weapon itself (Fig. e1.6). A precise range of fire (eg, 2 vs. 5 inches) cannot be determined from examination of the wound alone. Because soot can be removed with débridement or wound cleansing, its presence and configuration around the wound should be noted and photographed before débridement unless the patient's clinical condition precludes this attention to detail.

Intermediate-Range Wounds. Tattooing, or stippling, is pathognomonic for an intermediate-range gunshot wound. Tattooing appears as punctate abrasions and is caused by contact with partially burned and wholly unburned pieces of gunpowder (Fig. e1.7). Tattooing or stippling cannot be wiped away. Tattooing rarely occurs on the palms of the hands or soles of the feet because of the thickness of the epithelium.

Tattooing may occur as close as 1 cm to and as far away as 1.3 m from the weapon but is generally found at distances of 60 cm or less. The density of the tattooing and associated pattern depend on the length of the barrel, muzzle to skin distance, type of gunpowder, presence of intermediate objects, and caliber and type of ammunition. Clothing, hair, or other barriers may prevent tattooing from occurring. The presence of partially or entirely unburned pieces of gunpowder and gunpowder residues on clothing or skin aids in determining the range of fire. On rare occasion, pieces of gunpowder can penetrate thin clothing and leave punctate abrasions (Fig. e1.8).

Long-Range Wounds. The distant or long-range wound is inflicted from far enough away that only the bullet makes contact with the skin. There is no tattooing or soot. As the bullet penetrates the skin, the skin is indented, resulting in the creation of an abrasion collar, also termed an abrasion margin, abrasion rim, or abrasion ring (Fig. e1.9). This collar is an abraded area of tissue that surrounds an entry wound as the result of friction between the bullet and epithelium. The width of the abrasion collar varies...
Atypical Exit Wounds. A shored exit wound is a wound that has an associated false abrasion collar. If the skin is pressed against or supported by a firm object or surface at the moment the bullet exits, the skin can be compressed between the exiting bullet and supporting surface (Fig. e1.13). Examples of supporting structures include belts, floors, walls, doors, chairs, and mattresses.

Atypical Entrance Wounds. Atypical entrance wounds occur when a bullet encounters an intermediate object, such as a window, wall, or door, before striking the victim. The intermediate object may change the bullet’s size, shape, or path. Such changes can result in entrance wounds with large stellate configurations that mimic close-range or contact wounds (Fig. e1.11). Ricochet bullets may also cause atypical entrance wounds. Graze wounds are atypical wounds from tangential contact with a passing bullet.

Handgun Exit Wounds

Exit wounds are the result of a bullet pushing and stretching the skin from the inside out. The skin edges generally are everted, with sharp but irregular margins.

The size of the exit wound is determined by the energy transferred from the bullet to underlying tissue and by the bullet’s size and configuration as it exits the skin (Fig. e1.12). When a bullet enters the skin, its configuration may change from its usual nose-first attitude owing to tumbling and yaw. A bullet that exits the skin sideways, or one that has increased its surface area by mushrooming or transferring its energy to underlying bone, will have an exit wound larger than its entrance wound.

Fig. e1.10. Pseudotattooing, or punctate abrasions from glass fragments, not unburned gunpowder, on the medial aspect of the thigh associated with a gunshot wound. The leg was showered with glass fragments after the round penetrated the window pane.

Fig. e1.11. A, An atypical entrance wound from impact with a .40-caliber bullet. B, The projectile was deformed as it penetrated a windshield.
tattooing but, because of a number of variables, such as muzzle length, amount of power in a given cartridge, muzzle configuration, and type of gunpowder, the range of fire in rifle wounds is not as clearly defined as in handgun wounds. The determination of an exact range of fire for rifles and shotguns is best established through controlled testing performed by a firearms examiner at a crime laboratory.

High-velocity bullets with jackets and lead cores generally break up into hundreds of fragments, termed a lead snowstorm, on entering tissue, resulting in significant tissue damage (Fig. e1.15). If the tissue penetrated is deep, the bullet fragments may fail to exit and remain embedded. It is therefore possible to sustain an injury from a high-velocity round and not exhibit an exit wound. High-velocity rounds with steel cores will almost uniformly exit intact.

**Shotgun Wounds**

The massive damage caused by slugs may obliterate the abrasion collar usually associated with entrance wounds. Shotgun slugs will almost uniformly exit the body with large exit wounds.

**Clinical Features**

Patients with firearm injuries have varying presentations, depending on the anatomic location of the injury and type of weapon used. It is important to identify all wounds to guide the determination of the potential missile trajectory and anticipate the other possible injuries. It is also important to consider how the

No soot is present around the smaller exit wound. Exit wounds are not consistently larger than their corresponding entrance wounds.

**Fig. e1.13.** Shored exit wound with a false abrasion collar. This type of wound occurs when the skin in the region of the exiting bullet is in contact with a supporting structure (eg, wall, floor, mattress). The skin is slapped against the supporting structure, which results in a false abrasion collar.

**Centerfire Rifle Wounds**

Projectiles discharged from centerfire rifles have the potential to inflict massive tissue damage (see Fig. e1.2). Entrance wounds associated with high-velocity, centerfire projectiles do not significantly differ from those of handguns. Entrance wounds will generally exhibit abrasion collars or microtears on the skin surface (Fig. e1.14). Wounds will also have associated soot deposition and

Fig. e1.15. A snowstorm from a high-velocity rifle round. High-velocity projectiles have a tendency to fragment into hundreds of tiny particles on contact with bone. This fragmentation contributes to the massive tissue damage associated with these projectiles.

The imaging modalities used will differ, depending on the location of the injury. Details of the appropriate diagnostic strategies are outlined in the chapters on trauma (Part II of this text). In brief, most injuries will require computed tomography (CT) imaging to delineate the extent of tissue damage. A noncontrast CT scan of the head can show associated skull fractures, intracranial hemorrhages, or retained missiles. A CT angiogram of the neck is useful to evaluate for injuries to essential neurovascular or aerodigestive structures. Patients with persistent pain to the posterior neck with negative CT imaging may require magnetic resonance imaging (MRI) to evaluate further for ligamentous pathology. Thoracic injuries often mandate a CT chest scan to assess for injuries to the lungs, heart, and mediastinum, as well as to define the bullet trajectory. Chest x-rays are sensitive for pneumothoraces but are not sensitive or specific for mediastinal injury, which requires more advanced imaging. X-rays can also be used to diagnose diaphragmatic injuries when specific findings are present, such as a visualized herniated viscus (the collar sign) or a nasogastric tube in the stomach above the diaphragm. However, a negative x-ray cannot rule out diaphragmatic injury, and CT imaging is more sensitive and specific. Abdominal or genitourinary injuries will also require CT of the abdomen and pelvis to identify the tissues injured. It is important to keep in mind that thoracic and abdominal injuries occur concurrently in 6% to 42% of cases, with diaphragmatic injuries in 59%, and evidence of trauma to one body cavity should encourage imaging...
of the other. A CT urogram or cystogram may be indicated if there is a concern for upper tract or bladder injury respectively. Spinal cord or vertebral injuries are well visualized by MRI or CT, respectively—but note that the metallic nature of most bullets may preclude imaging with MRI.

**Differential Diagnosis**

There is a limited differential diagnosis for firearm injuries because the mechanism is usually known, often prior to the patient’s arrival to the ED. However, patients may sustain multiple injuries, so it is important to be vigilant to avoid missing subtle or smaller concomitant injuries. It is also critical to realize that bullets and bullet fragments may travel, embolize, or cause damage by way of the temporary cavity, so a change in the patient’s clinical condition should be trigger an appropriate reevaluation. For example, one case series has shown that an air rifle pellet embolizes to the internal carotid artery, resulting in stroke like symptoms. Another study has shown that delayed stroke symptoms could occur from thrombosis of the internal carotid artery due to the temporary cavity following a gunshot wound. These symptoms are often delayed (in the latter case, the patient was initially asymptomatic), so frequent reevaluation of these patients is valuable.

**Management and Disposition**

Again, management of patients with gunshot injuries varies by injury location. Resuscitation is key, with immediate and judicious use of crystalloid and/or blood as needed, as well as stabilization of the airway and actively bleeding wounds.

**Head and Neck Injuries**

In addition to resuscitative measures, it is important to limit hypoxia and hypotension in head-injured patients with a traumatic brain injury (TBI). Emergent operative procedures may be required to evacuate intracranial hematomas in patients in whom there is significant mass effect, shift, or other evidence of increased intracranial pressure. Neck injuries are managed with emergent intubation, as needed, and control of active hemorrhage. Vessel ligation might also be required if unable to control the hemorrhage with direct pressure. Damage to vital structures may necessitate emergent operative intervention. Patients with penetrating injuries to the neck may also require endoscopy, esophagoscopy, and/or bronchoscopy, depending on the path of the missile.

**Thoracic Injuries**

Decompression of pneumothoraces, hemothoraces, and hemorrhagic pericardial effusions is usually emergently required. An ED thoracotomy is performed for patients who present in cardiac arrest within 15 minutes of their injury or on arrival to the ED. Tension pneumothoraces or pericardial tamponade should be decompressed emergently, prior to advanced imaging. Mediastinal and aerodigestive injuries should be elucidated by esophagoscopy, bronchoscopy, and possible angiography. Suspected diaphragmatic injuries should also be evaluated with laparoscopy because patients may initially be asymptomatic but may develop bowel herniation and eventual strangulation of the herniated tissue even years later.

**Abdominal Injuries**

Gunshot wounds to the abdomen can be managed expectantly if the patient is stable with no injuries to the peritoneal cavity or with moderate solid organ injuries (grades 1–3 liver or splenic lacerations). However, unstable patients or those with concomitant bowel injuries (including evisceration) or severe splenic or liver lacerations (grade 4 or 5) will require emergent exploratory laparotomy. Genitourinary injuries are often managed after other life-threatening injuries have been addressed, aside from severe renal lacerations (grade 4 or 5), which may require nephrectomy. Urethral injuries are managed with Foley catheter placement before or after the appropriate diagnostic modalities have been performed (retrograde urethrography or retrograde cystourethrography). Intrapelvic bladder injuries are managed operatively, whereas extraperitoneal injuries are managed with Foley catheter placement and decompression.

**Extremity Injuries**

Management of these injuries involves irrigation, debridement of devitalized tissue, and traction or splitting of broken extremities. Bullet removal is only required in certain cases. It is required for missiles in contact with synovial fluid or within intervertebral disks, given the potential for dissolution and resulting systemic symptoms. Patients should also be monitored for compartment syndrome, vascular, or neurologic injuries, especially following high-energy injuries. Operative intervention is required for patients with unstable fractures, fractures with exposed bone, compartment syndrome, or vascular injuries requiring repair. Transabdominal injuries with pelvic fractures also mandate prophylactic antibiotics.

High-energy gunshot wounds with associated fractures are treated as open fractures and are generally treated with prophylactic antibiotics because contaminants can be sucked into the wound due to cavitation. Low-energy injuries can be managed as closed fractures with superficial débridement and prophylactic antibiotics, although the literature suggests that there are low infection rates with or without antibiotics. Intraarticular fractures also appear to warrant débridement.

**Soft Tissue Injuries**

Soft tissue wounds are managed with irrigation, but wounds are left open. Prophylactic antibiotics are not routinely recommended. However, because high-energy injuries and shotgun wounds produce a significant amount of devitalized tissue, they often require operative débridement. Aggressive débridement along the wound tract or path of the projectile is not routinely recommended.

Tetanus vaccinations should be updated and tetanus immunoglobulin given to those without prior immunity. Bullet removal is also only indicated for certain extremity injuries (see earlier), for missiles with the potential to embolize, or for those in the myocardium. Prophylactic antibiotics are also not routinely recommended, despite the fact that bullets wounds are not sterile. Indications for prophylactic antibiotics are grossly contaminated wounds, abdominal wounds with hollow viscus injury, intraarticular injuries, intracranial injuries, and high-energy gunshot injuries.

**Evidence**

A victim’s clothing may yield information about a bullet’s range of fire and help distinguish entrance from exit wounds. Clothing fibers will deform in the direction of the passing projectile. Gunpowder residues and soot will deposit on clothing as they do on skin. Residue may be invisible to the naked eye, but nitrites and vaporized lead can be visualized with standard forensic staining techniques. Some bullets, as they make initial contact with clothing, leave a lead or lubricant residue that is termed bullet wipe.
Articles of clothing removed from a wounded patient need to be placed in separate paper bags to avoid cross-contamination of evidence.1

The bullet, bullet jacket, and cartridge case are invaluable for identifying or excluding a suspect weapon. When a weapon is discharged, the discharge imprints multiple microscopic marks on the side of the bullet and on the bottom or side of the cartridge case. The markings result from the bullet’s contact with the tool marks, or rifling, in the gun’s barrel. These marks are unique to each barrel and are reproducible. These marks are the gun’s fingerprint, so to speak. Cartridge case marks are from contact with the firing pin, breech lock, magazine of semiautomatic weapons, and extractor and ejector mechanisms. These microscopic fingerprints can be obliterated by removing a bullet with hemostats or pickups. Therefore, as mentioned earlier, bullets should be handled with gloves, and the tips of surgical instruments should be covered with gauze (Figs. e1.16 and e1.17) or plastic tips (so-called suture booties) to ensure the preservation of these microscopic marks. It is not necessary to place initials or other markings on the bullet if adequate notes are made in the patient’s medical record regarding the chain of custody.7

Radiographs also help locate retained projectiles and may be of evidentiary value in determining the number of projectiles and the direction of fire. It is important to maintain a chain of custody to preserve as much evidence as possible. This should also be documented, ideally on a chain of custody form. There is a new trend of forensic care programs in EDs to facilitate this process. It uses a concept similar to that of sexual assault nurse examiner programs, in which a dedicated forensic staff member is responsible for evidence collection, which should theoretically improve documentation and collection due to her or his specialized training.

**Conclusions**

The impact of firearm injuries cannot be understated, and it is a tremendous public health issue.19 Not only do firearms result in significant injuries or fatalities, but they can also have a significant impact in other areas, such as the number of productive years lost for adults and missed school for children and adolescents. They also contribute to health disparities.21 One study has found that a disproportionate amount of resources is required for gunshot wound patients who require emergency medical services activation.50 Economically, the estimated lifetime costs for firearm-related injuries (resulting in death, hospitalization, or ED evaluation alone) amounted to over $45 billion in 2010.15 This does not take into consideration the emotional impact that fatalities have on families and communities as a whole. Therefore, the focus should be on prevention as much as possible to avoid incurring such costs.

A number of organizations, including the American College of Emergency Physicians, American College of Physicians, American Pediatric Surgical Association, and American Academy of Pediatrics have all noted that firearm violence is a significant public health problem and, as such, have advocated for a public health approach to reduce the burden of firearm-related injuries and deaths. Measures suggested include stricter background checks, stronger legislation regarding illegal firearm sales, and limitation of access to children and those with a history of mental illness or substance abuse, as well as patient education about firearm injury prevention, especially in patients at risk.15,21 There is also support for using the ED or outpatient visit following nonfatal injuries as teachable moments to educate patients about future firearm violence.19 Education of emergency clinicians about appropriate counselling methods may be beneficial, as shown in one recent study with a pediatric training program.37 Such a public health approach has been successful in reducing the fatalities from motor vehicle trauma and may be a good model to apply to firearm injuries to reduce the burden on society.

**FORENSIC ASPECTS OF PHYSICAL ASSAULT**

**Perspective**

Interpersonal violence is a leading cause of death in the United States, particularly among children, adolescents, and young adults. Annually, in the United States, there are more than 16,000 homicides and 1.6 million nonfatal assault injuries requiring treatment in the ED.38 Rates of violence vary by age, gender, ethnicity, and geographic location. Homicide is the leading cause of death for non-Hispanic blacks from age 1 through 44 years, whereas it is the fifth most common cause among non-Hispanic whites in the same age group. The high rate among African Americans is primary driven by the remarkably high rates among males between
the ages of 15 and 34 years. Differences in child maltreatment rates, as well as other forms of violence, are attributable to underlying risk factors, such as poverty. Urban areas have higher homicide rates than suburban or rural areas. Overall, the proportion of assaults resulting in death has declined markedly since the 1960s, thought to be due to the availability of organized trauma care. It is the emergency clinician’s responsibility not only to care for these patients clinically, but also to assist law enforcement with thoughtful documentation of injuries, evidence preservation, and collection.

Accurate documentation of the anatomic location of the injuries makes it easier to determine the implement, tool, or weapon responsible for producing each wound. Descriptions of wounds should include their shape, precise body location, and measured size. Specific characteristics should be noted, such as the presence of other materials, coloration, and patterned injuries. Such pattern injuries of abrasions or contusions may retain some features of the impacting object, possibly allowing it to be identified. Every weapon leaves a mark, design, or pattern stamped or imprinted on or just below the epithelium. The epithelial imprints of these weapons, termed pattern injuries, are consistently reproducible. These injuries are classified into major categories according to their source—blunt force, sharp force, thermal, and chemical.

Correct terminology is also important when describing wounds. When referring to blunt force wounds, these injuries are termed lacerations caused by blunt force trauma, as opposed to an incised wound or cut, which is the violation of epidermis caused by a sharp instrument that is longer than it is deep. Stab wounds are deeper than they are wide. Also, wounds and bruises should be described as they are seen, and no comment on age or time of occurrence should be documented.

When cutting clothes, avoid cutting through defects caused by sharp force injuries. Clothing items should be placed into paper bags, labeled, sealed, and then turned over to law enforcement. Plastic bags retain moisture and promote the growth of bacteria, which could degrade DNA evidence. Sharp force weapons that are recovered should be wrapped in craft paper or cardboard to protect them from causing injury and sealed for evidence collection.

Conclusions regarding the alleged perpetrator and the mechanism of injury should generally be avoided.

**Blunt Force Pattern Injuries**

The most common blunt force injury is the contusion, along with abrasions and lacerations. A weapon with a unique shape or configuration may stamp a mirror image of itself on the skin (Box e1.1).

**Pattern Contusions**

A blow from a linear object leaves a contusion that is characterized by a set of parallel lines separated by an area of central clearing (Fig. e1.18). The blood underlying the striking object is forcibly displaced to the sides, which accounts for the pattern’s appearance (Fig. e1.19).

Circular or linear contusions suggest abuse or battery. Circular contusions 1.0 to 1.5 cm in diameter are consistent with fingertip pressure and grab marks (Fig. e1.20). One commonly overlooked anatomic location for fingertip pressure contusions is the medial aspect of the upper arm. The sole of a shoe from a kick or stomp may also leave a pattern contusion that can assist in identifying the assailant (Fig. e1.21).

Some injuries allegedly occur during police custody. Specific pattern contusions can include parallel contusions from a flashlight or night stick. Handcuff or shackle marks are narrow parallel contusions or abrasions on the wrists or ankles. Handcuff and shackle marks are generally more prominent on the lateral aspects of the extremity.

![Fig. e1.18. A direct blow from a linear object results in a pattern contusion with central clearing surrounded by parallel linear contusions. The blood directly beneath the impacting object is displaced laterally and accounts for the distinctive contusion.](image1)

![Fig. e1.19. Pattern contusion with parallel lines and central clearing from contact with a baseball bat.](image2)
The emergency clinician should not render an opinion on the age of a contusion. The development of a contusion is based on a number of variables, such as the amount of blunt force applied to the skin, vascularity of the tissue, oxygenation of the extravasated hemoglobin, depth of the hematoma, skin tone, and amount of blood that escapes into the surrounding tissue. As a result, no reproducible standard for the dating of a contusion is possible based on its color.

**Pattern Abrasions and Lacerations**

A bite mark may appear as a pattern contusion, abrasion, or combination of both (Fig. e1.22). Bite marks vary greatly in the quality of their identifiable features, depending on the location of the bite and motion of the teeth relative to the skin. Some bite marks may not be readily identifiable as such and may appear as nonspecific contusions, abrasions, or contused abrasions. Generally, adult mikes have an interdental distance of more than 3 cm.

When an acute bite mark is identified, care should be taken not to wash away potential evidence. The skin surface should be swabbed with a sterile cotton-tipped applicator moistened with sterile saline. DNA from buccal cells may also be deposited over an acute bite mark.

A laceration is defined as a tear in the skin produced by blunt trauma and characteristically displays tissue bridges and crushed wound margins (Fig. e1.23).

The emergency clinician should not render an opinion on the age of a contusion. The development of a contusion is based on a number of variables, such as the amount of blunt force applied to the skin, vascularity of the tissue, oxygenation of the extravasated hemoglobin, depth of the hematoma, skin tone, and amount of blood that escapes into the surrounding tissue. As a result, no reproducible standard for the dating of a contusion is possible based on its color.

**Sharp Force Pattern Injuries**

An incised wound is longer than it is deep, and a stab wound is defined as a puncture wound that is deeper than it is wide. The
wound margins of sharp force injuries are clean and lack the abraded edges and tissue bridges of injuries resulting from blunt forces.

Forensic information can be gathered during the examination of a stab wound. Some of the characteristics of a knife blade, single-edged or double-edged, can be determined from visual inspection (Fig. e1.24A, B). Additional blade characteristics, such as serrated versus sharp, can be seen if the blade was drawn across the skin during its insertion or withdrawal (see Fig. e1.24C).

Patients with self-inflicted wounds may visit the ED claiming an accident, self-defense, or assault. When the patient history, injuries, and forensic evidence are not consistent, the forensically informed emergency clinician is in a unique position to extrapolate the truth. With an understanding of how to identify the patterns of self-inflicted knife wounds, the emergency clinician can provide appropriate referrals, conserve resources, and assist law enforcement in the investigation of an alleged crime.

When a patient claims to have been assaulted as the victim of a crime, his or her injuries become physical evidence. It is important for the treating emergency clinician, who may be called as an expert witness, to recognize patterns of self-inflicted injury and to distinguish self-inflicted wounds from those sustained during an assault (Fig. e1.25; Box e1.2). One study of sharp force fatalities that were autopsied has shown that certain patterns may be used to distinguish these injury patterns. Homicide cases show other associated stab and cut wounds or defensive wounds, whereas self-inflicted cases predominantly show isolated cut wounds or associated superficial hesitation marks. Defense injuries most frequently present as cuts on the hands, followed by the forearms, typically on the extensor sides of the forearms and hands, as well as the flexor sides of fingers. Wounds located at the head, limbs, hand, neck, or back are predictive of a homicide, whereas wounds located solely at the anterior parts of the trunk, neck, or forearms are more likely to be self-inflicted. The presences of bone or

**Fig. e1.24.** A, A single-edged knife blade will cause a wound to be formed with a sharp edge and a dull edge. If the blade penetrates to its hilt, a hilt mark may be seen overlying the sharp edge. B, Single-edged stab wound. C, Single-edged stab wound made by a serrated blade. Abrasions from the blade’s serrated edges are seen on the left margin of the wound.

**Fig. e1.25.** The presence of multiple, parallel, superficial incised wounds, sometimes termed hesitation marks, are indicators of self-inflicted wounds.

**BOX e1.2**

**Characteristics of Self-Inflicted Knife Wounds**

- Multiple superficial incisions located on the anterior trunk, arms, and face
- Multiple superficial stab wounds located on the anterior trunk, arms, and face
- Parallel incisions, in close proximity to each other, on the nondominant side of the body
- Sparing of sensitive body areas
- Linear or curved incisions toward the hand inflicting the wound
- Intact clothing covering the wound
- Evidence of prior wounds in repeat offenders
cartilage wounds is predictive of homicide, and their absence is predictive of self-inflicted.45

**Thermal Pattern Injuries**

A thermal pattern injury is a common form of abuse or battery, particularly in pediatric patients. They comprise about 5% to 22% of all physical abuse,41 and pediatric burns represent 6% to 20% of all abuse cases.41 The history should include the position of the patient relative to the thermal source. This information will help determine whether the injury was intentional or accidental. The location of the burn may also be helpful in delineating the intent of the burn; burns to the gluteal area or perineum are very rarely accidental, whereas burns to the hands and upper trunk are common with unintentional injuries.41

Intentional burns tend to be deeper and well demarcated and are often due to hot objects, such as curling irons, cigarettes, or hot liquids.41 A sharp or clear line of demarcation between burned and unburned tissue characterizes immersion or dipping burns. In contrast, splash burns are characterized by an irregular or undulating line or by isolated areas of thermal injury, usually round or oval in shape, caused by droplets of hot liquid.

The severity of thermal or scald injury depends on the length of contact time and the temperature. Skin damage can result from a number of different mechanisms whereby temperatures in excess of 49°C (120°F) cause cellular damage but, again, the exact temperatures required depend on contact time.42 Law enforcement routinely measures the household’s or institution’s water temperature in any investigation involving a scald injury.

It is important to be attentive to concomitant injuries in burn patients, particularly those who are victims of significant violence. These patients may sustain associated injuries, such as fractures, that need to be addressed emergently.44

**Chemical Injuries**

Chemical injuries are a rare means of assault in the United States and Europe but have been noted in countries such as Bangladesh and Jamaica. The victims tend to be female, often following domestic disputes.43 The most commonly used agents are those found around the home, such as car battery acid, which is usually thrown at the victim. The head, face, and neck are predominantly affected but the fluid may spread to the chest and trunk as well.43 Patients develop findings consistent with burns from acids or alkalis because cellular damage results from coagulative or liquefactive necrosis, respectively.

Primary management is similar to that for other chemical injuries and consists of prompt removal of contaminated clothing or other materials as soon as possible and irrigation of the affected area with copious amounts of water; tap water has been shown to be adequate for this purpose. Patients may also require rapid resuscitation with intravenous fluids and pain control, with or without airway management. These patients may also develop a significant electrolyte abnormality, such as metabolic acidosis or hypocalcemia, which require close monitoring and treatment.

**FORENSIC ASPECTS OF MOTOR VEHICLE TRAUMA**

**Perspective**

Globally, road traffic injuries are estimated to be the eighth leading cause of death.44 Half of the world’s road traffic deaths occur among so-called vulnerable road users, which are motorcyclists (23%), pedestrians (22%), and cyclists (5%), compared with 31% of deaths among car occupants.45 In vulnerable road users struck by motor vehicles, there is evident gender disparity, with more males affected. In addition, infrequent helmet use, riding against traffic, and use of electronic devices while driving are important factors.46 In high-income countries, the proportion of deaths in those older than 70 years is noticeably greater than in low- and middle-income countries, likely due to longevity, combined with the greater risks posed by reduced mobility and frailty. Young adults between 15 and 44 years account for 59% of global road traffic deaths, with 77% of those deaths occurring in men.47 Substance abuse and distracted driving, particularly with cell phone use, are dominant patterns seen in high-risk behavior in motor vehicle crashes (MVCs) and not wearing a motorcycle helmet is deadly for victims of motorcycle crashes. Devastating brain injuries are the leading cause of mortality in MVCs and motorcycle-related deaths.48-50 For pedestrians and bicyclists, the collision speed of the vehicle and protective devices are obvious factors that influence injury outcome.49-52 Patterns of injury differ according to the mechanism of injury.

**Motor Vehicle Collisions**

In MVCs, the head and thorax are the most frequently injured body regions.51,52 MVCs are associated with approximately 60% to 70% of all cases of blunt chest trauma and are the most common cause of pulmonary contusions.53 Occupants impact against the dashboard and steering wheel and are more likely to sustain torso injuries.54 Frontal and near-side crashes are most frequently associated with pulmonary contusion. Occupant weight, body mass index, and number of rib fractures are positively correlated with pulmonary contusion volume. The initial mechanical insult to the chest is followed by a secondary inflammatory response that extends the injury and has been shown to be predictive of ventilatory support, acute respiratory distress syndrome, and pneumonia.55 Although women are less often involved in MVCs when compared to men, it has been shown that belt-restrained female drivers involved in an MVC are more susceptible to severe injuries, particularly of the chest and spine, when compared to male drivers.56

**Motorcycle Collisions**

In the United States, there has been an overall decrease in the injuries sustained by young adult motorcyclists and an increase in the injuries sustained by middle-aged and older adult motorcyclists.57 For middle-aged and older adult motorcyclists, MVCs are associated with approximately 60% to 70% of all cases of blunt chest trauma and are the most common cause of pulmonary contusions.53 Occupants impact against the dashboard and steering wheel and are more likely to sustain torso injuries.54 Older adult motorcyclists had the highest rates of hospitalization, followed by middle age, than younger adults. Similarly, older adult motorcyclists had high injury severity scores compared to younger adults.55 With increasing age, older adults and middle-aged adults were more likely to sustain internal organ injuries, with head and chest injuries associated with the lowest rate of survival.55

**Evaluation of Motor Vehicle Collisions**

Law enforcement officials investigating an incident involving serious or fatal injuries from a motor vehicle or pedestrian collision may benefit from information regarding injury patterns and the collection of trace evidence from the victim. This information can help determine whether an occupant was a driver or passenger. It may help identify a suspect vehicle involved in a hit and run pedestrian collision or a pedestrian’s position (standing or lying) when struck in the roadway.

Determination of a vehicle occupant’s role may be simple (eg, if the driver is pinned behind the steering wheel) or complex (eg, if the vehicle’s occupants are ejected). Many impaired drivers claim to be passengers. Short-lived evidence or pattern injuries that might be destroyed or altered in the delivery of patient care should optimally be preserved and photographed.

An opinion on an occupant’s position should be avoided because an occupant’s role is difficult to determine based solely
on history and physical findings in the ED. Such an opinion is best rendered by someone who has examined the scene, vehicle, other occupants, and trace evidence, has reviewed postmortem examinations, and has had the collision reconstructed to determine vehicle dynamics (Box e1.3).

Pattern Injuries

Matching pattern injuries with components within a vehicle often reveals an occupant’s position during a portion of the vehicle’s collision sequence. Common pattern contusions, abrasions, and lacerations are seen from steering wheels, air bags, air bag module covers, window cranks, radio knobs, door latches, dashboard components, and front and side window glass. An occupant’s movement and subsequent contact with a vehicle’s components are dictated by the forces applied to the vehicle through its interaction with the environment. Vehicle occupants, restrained or unrestrained, will initially move toward the primary area of impact.

A deployed air bag may induce a pattern abrasion to the face, cornea, forearms, or other exposed tissue. Pattern lacerations, specific fracture patterns, and amputations are seen when the deployed air bag module cover impacts the hand or forearm (Fig. e1.26). The correlation of these injuries and transfer of DNA from the driver or passenger to the deployed air bag are helpful in assessing an occupant’s role as driver or passenger.

Laminated glass (windshields) and tempered glass (side and rear windows) produce pattern injuries. The windshield has two layers of glass laminated together with a thin layer of clear plastic sandwiched between. Laminated glass breaks into shards on impact and causes linear incised wounds. Tempered or safety glass is a single layer of glass that breaks into small cubes when fractured, imparting a dicing pattern to the skin (Fig. e1.27).

Trace Evidence

Clothing, shoes, and biologic standards (eg, hair, tissue, blood) may determine an occupant’s role. The soles of leather shoes may reveal the imprint of the gas or brake pedal (Fig. e1.28). Preservation of clothing permits the comparison of clothing fibers with...

**BOX e1.3**

**Evidence Collection—Driver Versus Passenger**

**VICTIM**
- Examine for Pattern Injuries
  - Steering wheel contusion
  - Radio knob contusion
  - Window crank contusion
  - Striated incised facial wounds
  - Dicing wounds

- Examine Clothing for Transferred Material
  - Glass (front and side windows)
  - Fibers
  - Pedal imprint on shoe
  - Dashboard components

- Collect Biologic Standards
  - Hair
  - Blood

- Collect Clothing Standards
  - Damage

**VEHICLE**
- Examine for Pattern Damage
  - Steering wheel
  - Radio, knobs, dashboard
  - Window crank, side door
  - Windshield (laminated glass)
  - Side and rear window (tempered glass)

- Collect Standards
  - Glass
  - Carpets and seats
  - Gas and brake pedals
  - Broken dashboard components

- Examine for Transferred Material of Pedestrian
  - Hair on windshield and components
  - Blood on windshield and components

- Examine for Transferred Material on Car Occupants
  - Fabric fibers
  - Imprinted fabric pattern

---

*Each article of clothing should be collected in a separate paper bag. This avoids cross-contamination, and wet material will dry. Do not collect evidence in plastic bags because moisture will condense within the bag and may degrade biologic material.
*Each article should be marked with the patient’s name, item collected, date and time collected, location of collection, name of the collector, and name of law enforcement official to whom the evidence was given. This information will preserve the chain of custody.
those fibers transferred to vehicle components during the collision. Imprints of fabric may also be transferred to components within the vehicle, including the steering wheel. Contact with the windshield often transfers hair and tissue to the glass. Glass collected from within a patient's wound can be matched with a particular window within the vehicle. Air bags can be an excellent source of trace evidence. Examples of transferred evidence include skin, blood, makeup, and hair (Fig. e1.29).

**Evaluation of Pedestrian Collisions**

Pedestrians impact against various parts of the vehicle and ground and therefore sustain injuries to their arms and legs. The injury severity of pedestrians increases exponentially with increased impact speed of the offending vehicle. Crossing at uncontrolled midblock locations results in greater injury severity compared with crossing at a signalized intersection. Alcohol use is a significant risk factor for pedestrians stuck by motor vehicles because these patients are more likely to cross the street in an unsafe manner and sustain more serious injuries. In pedestrians who were seriously injured or killed, driver failure to yield and driver inattention were cited as significant contributing factors. Pedestrians are at high risk for severe TBI, specifically intracranial hemorrhages and contusions and significant skull fractures.

**Pattern Injuries**

When struck by the front of a vehicle, a standing adult will sustain bumper injuries, which include open and closed fractures of the tibia and fibula, soft tissue damage, and pattern injuries from vehicle components and hardware.

The height of bumper injuries, measured from the heel and including the height of the patient's shoe, can be correlated with the height of the vehicle's bumper to determine whether the vehicle was braking at the moment of impact. Application of the brake results in the dipping of a vehicle's front end. The presence or absence of braking may help determine the driver's intent. The presence of bumper injuries at one height on one leg and at another height on the other may indicate that the pedestrian was walking or running at the moment of impact, with one leg elevated. Examination may show lateral striations or abrasions when a patient has been dragged.

A victim who is struck from behind may have pattern contusions on the calf or thigh (Fig. e1.30), whereas pattern contusions from a grill on the anterior aspect of the thigh indicate that the

---

**Fig. e1.28.** Imprint of a brake pedal on a leather-soled shoe. This information will assist in determining the occupant's role and whether the patient's foot was on the brake or accelerator pedal at the moment of impact.

**Fig. e1.29.** Occupant contact with the air bag often results in the transfer of trace evidence. The presence of blood, tissue, hair, and makeup will assist in the determination of the seating arrangement of a particular occupant.

**Fig. e1.30.** A, A pattern imprint contusion on the posterior aspect of a pedestrian's right thigh was the result of contact with the vehicle's grill. The location of the contusion provides information about the configuration of the patient at the moment that the car struck him. The patient was struck from the rear. B, The grill of the striking vehicle.
to investigating law enforcement agencies specific information regarding a victim or suspect, without patient consent. Section 45 CFR 164.512 permits the release of protected health information, without a court order, “in response to a law enforcement official’s request for such information for the purpose of identifying or locating a suspect, fugitive, material witness, or missing person.” A hospital or emergency clinician may disclose the information listed in Box e1.5 only to an investigating law enforcement officer.

Pedestrian was standing and facing the vehicle. Pedestrians struck by a glancing portion of a vehicle may also display a pattern injury (Fig. e1.31). Victims who are run over may display a tire tread pattern (Fig. e1.32). Tire marks and the absence of bumper injuries suggest that the patient was supine or prone in the roadway before he or she was run over (Box e1.4).

**Law Enforcement Exemptions to the Health Insurance Portability and Accountability Act**

Title 45, Part 164, of the Health Insurance Portability and Accountability Act (HIPAA) of 1996 permits hospitals to disclose

---

**KEY CONCEPTS**

- Knowledge of wound mechanics and production, as well as wound appearance, can provide practicing emergency clinicians with important clues regarding the forensic interpretations of injuries.
- Wounds and injuries should be diagrammed and photographed.
- The medical record should accurately document objective findings associated with a patient’s wounds. Emergency clinicians should not speculate about their mechanism or the cause.
- Any evidence collected during the course of treatment must be documented in the medical record, including to whom the evidence was given, for the chain of custody to be preserved.

**CHAPTER e1: QUESTIONS & ANSWERS**

**e1.1. When documenting a gunshot wound, it is important to do which of the following?**

A. Describe the appearance, physical characteristics, and location of wounds.

B. Describe the bullet trajectory.

C. Determine the type of bullet used.

D. Estimate the caliber of the bullet.

E. Interpret the wounds as “entrance” or “exit.”

**Answer:** A. Emergency clinicians should not identify wounds as “entrance” or “exit.” Instead, their charting should include a detailed description, using appropriate forensic terminology, of the wound’s characteristics and location without speculating about its function or the caliber or type of bullet (projectile) used to create it.

**e1.2. A young woman presents with a gunshot wound to her arm. She has good pulses and sensation distal to the wound. On inspection of the wound, you notice a black material, which can be wiped away, surrounding the wound. This most likely indicates which of the following?**

A. The barrel of the gun was between 12 and 24 inches (intermediate range) away.

B. The barrel of the gun was within 6 inches (close range) of the skin.

C. The distance between the barrel of the gun and the skin cannot be determined.

**Answer:** B. In close-range wounds (6 inches or less), the carbonaceous material created from the burning of gunpowder will deposit on skin and clothing. The carbonaceous material is called soot and can be easily wiped away from wounds.

**e1.3. Tattooing, associated with a gunshot wound of entrance, is pathognomonic for which of the following?**

A. Close-range wound

B. Contact wound

C. Distant-range wound

D. Indeterminate-range wound

E. Intermediate-range wound

**Answer:** E. Tattooing, or stippling, is pathognomonic for an intermediate-range gunshot wound. It appears as punctate abrasions and is caused by contact with partially burned and wholly unburned pieces of gunpowder. Tattooing or stippling cannot be wiped away and will gradually resolve over several days. Intermediate range is defined as 48 inches or less.

**e1.4. A 23-year-old woman presents after having been physically and sexually assaulted by an unknown assailant. In addition to multiple abrasions and brown contusions, she has a bite mark on her left shoulder. Which of the**

---
CHAPTER e1 Forensic Emergency Medicine

C. Maintain a chain of evidence.
D. Place each article of clothing in a separate paper bag.
E. Use metal forceps to handle a bullet to prevent contamination.

Answer: E. Never remove a bullet with metal hemostats or pickups because metal tools can obliterate the microscopic markings (the telltale fingerprint) of the gun from which it was shot. A victim’s clothing may hold the answer to critical questions, such as “How far away was the assailant who fired the weapon?” and “Which hole is the entrance and which the exit?” Articles of clothing removed from a wounded patient should be placed in separate paper bags to preserve the trace evidence on them and to avoid accidentally transferring evidence from one article to another (cross-contamination). Always cover a patient’s hands with paper bags when the presence of soot is suspected. A gunshot residue test may determine whether a victim or suspect has been in close proximity to a weapon that has been fired. Factors that decrease the sensitivity of gunshot residue tests include washing the skin with alcohol or Betadine.

e1.5. When managing a gunshot wound victim, which of the following is not important for forensic evidence collection?
A. Do not clean the hands with alcohol or Betadine.
B. If soot is noted on the hands of the victim, cover with paper bags.
C. Maintain a chain of evidence.
D. Place each article of clothing in a separate paper bag.
E. Use metal forceps to handle a bullet to prevent contamination.

Answer: A. When an acute bite mark is identified, take care that critical evidence is not washed away. The skin surface should first be swabbed with a sterile cotton-tipped applicator moistened with sterile saline. Swabbing the area may reveal the assailant’s DNA present in dried saliva. Remember, a contusion’s color is never a predictor of its age. The emergency clinician may be asked to render an opinion regarding the age of a contusion. Because contusions develop as a result of multiple variables, there is no reproducible standard for dating them.

Firearm-Related Injuries

Emergency Medicine Leadership: Advocacy of Public Policy

KEY CONCEPTS

- The Haddon Matrix addresses injury prevention by focusing on the environment, agent inflicting harm, and at-risk populations. Key tenets to this injury prevention model include understanding of the following: (1) injuries are predictable; (2) they follow typical patterns (e.g., by age or gender); and (3) reliance solely on human factors for prevention has significant limits.
- The E-code is a system for identifying the cause of injury according to the International Classification of Diseases, Clinical Modification, and allows for systematic tracking of harmful agents.
- Proper use of lap and shoulder belts reduces the risk of death and severe injury to front seat passengers by 50%.
- Ten percent of fatal motor vehicle collisions and 17% of injury collisions are associated with distractions.
- Hospital-based violence intervention programs have been shown to decrease recidivism to the emergency department for recurrent violent injuries and decrease recidivism to the criminal justice system; hospital-based violence intervention programs have been found to be cost-effective.
- Firearm-related injuries are more prevalent among countries with higher rates of gun ownership. The US has the highest rate of gun ownership, with 89 guns/100 persons and the highest mortality rate attributed to firearm injuries of developed countries (e.g., 40 times higher than that of the UK).

CHAPTER e2

Injury Prevention and Control

Katherine Bakes

PRINCIPLES

Over 40 million people are treated in US emergency departments (EDs) for injuries annually, and approximately 30% of ED visits is injury-related. Injury is the fourth leading cause of death for all age groups and the leading cause for those aged 1 to 44 years (Table e2.1). The major causes of injury include falls, motor vehicle collisions (MVCs), gunshots, suffocation, and poisonings. In addition to the emotional cost of disability and lost lives, the monetary cost of injury-related medical care in the United States is estimated at approximately $150 billion annually. Because the emergency care system may be the injured patient’s only contact with the health care system, emergency clinicians have an opportunity to provide interventions and secondary prevention services.

History of Injury Prevention

Decreasing personal injury is a goal of modern public health. However, until the 1950s, unintentional injuries were attributed primarily to human error, and prevention was based on educating people to act safely. Safety design flaws were not considered when manufacturing roads, motorized vehicles, and other consumer products. From a public health perspective, this is analogous to supplying untreated tap water to homes and relying on educating people to purify their drinking water to prevent cholera.

In the 1920s, attributing vehicle collisions to poor driver performance led to mandatory licensing of drivers. In the 1930s, when it was learned that vehicle collisions could be caused by mechanical factors, President Roosevelt called for automobiles to be made more “crashworthy.” In 1942, Hugh DeHaven, a former World War I pilot turned physiologist, pondering his own survival in an airplane crash when another occupant had been killed, suggested structural provisions to vehicles that would reduce injuries in collisions. Also in the 1940s, an epidemiologist named John Gordon suggested that injuries have epidemic patterns, seasonal variation, long-term trends, and demographic distribution and can be examined with methodologies applied to infectious diseases. Gordon also believed that similar to other diseases, injury results from the interaction of the agent inflicting harm, host, and environment, a concept known as the epidemiologic triad.

In the 1960s, injury analysis began to consider three phases—preinjury, injury, and postinjury, allowing specific interventions to target specific phases. William Haddon, the first physician administrator for the National Highway Traffic Safety Administration (NHTSA), developed a comprehensive public health framework for injury prevention in 1970, referred to as the Haddon Matrix. In this model, modifiable factors include risk factors of the individual and the environment, as well as risks of the agent inflicting harm (eg, motor vehicles).

In 1985, the publication Injury in America: A Continuing Public Health Problem, by the National Research Council and Institute of Medicine, called on leaders in public health and the health care community to address the injury epidemic. With the establishment of the National Center for Injury Prevention and Control (NCIP) in the Centers for Disease Control and Prevention (CDC), injury prevention was adopted by the disease control community. In 2009, the NCIP published its research agenda, which included the need for acute care injury research.

Current State of Injury Prevention

Prevention of injury requires principles that have been successfully applied to other diseases, necessitating a broad interdisciplinary approach, including the medical community, public health, policy makers, law enforcement, and educated citizens (Box e2.1). Similar to other disease models, risk of injury is dependent on host factors (eg, seat belt use), external human factors (eg, driver from another car runs a red light), and environmental factors (eg, an icy road). Effective injury prevention strategies include (1) decreasing environmental risk factors, (2) enhancing protective factors, and (3) removing or modifying physical risks (eg, gun control).

Injuries are preventable. Understanding the risks of injury is paramount for developing prevention strategies and improving outcomes. Individual risk factors comprise static (or fixed) and dynamic (or changeable) risk factors. Static factors include age, gender, size, current stage in development, and past traumatic events; dynamic factors include mental or behavioral dysfunction amenable to therapy; substance use, social influences (eg, positive or negative peer influences), and other lifestyle choices (eg, decision whether to own or carry a weapon). Risks for injury and death vary by age (see Table e2.1). Environmental factors can also be modified to reduce injury risk, such as implementing safer road designs and lighting to prevent MVC g-force, removing throw rugs to prevent falls, placing fences around pools and railings around elevated surfaces, and separating bicycle paths from roadways. For children, effective strategies to reduce the risk of any injury should take into account the child’s developmental stage.

As defined above, the Haddon Matrix addresses injury prevention by focusing on the environment, agent inflicting harm, and at-risk populations. Table e2.2 illustrates use of the Haddon Matrix to reduce MVC injuries. Key tenets to this injury prevention model include understanding of the following: (1) injuries are predictable; (2) they follow typical patterns (eg, by age or gender); and (3) reliance solely on human factors for prevention has significant limits. After key collaborations are formed, injury countermeasures can be implemented using one of the three Es: education, enforcement of laws, and engineering modification of hazardous devices and environmental conditions.

Traditionally, emergency clinicians have focused on treating the patient after an injury has occurred. However, injury control techniques can be incorporated into emergency medicine practice. Recognizing that the emergency department (ED) provides a unique opportunity to identify and intervene in high-risk behaviors, many EDs now provide targeted risk assessments and clinically based interventions. Some of these assessments and interventions are mandated by federal regulators (eg, The Joint Commission requires EDs to have written protocols in place for identifying and treating survivors of domestic violence). Injury Control in Emergency Medicine Practice

**CLINICAL PREVENTIVE SERVICES**
- Document injury information in the medical record.
- Ensure that medical records of injury cases contain E codes.
- Assess behavioral and comorbid risk factors for future injury.
- Provide risk screening, counseling, and referral.
- Assess biomechanical risk factors in individual patients.
- Use biomechanical risk factors for directed evaluation of injured patients.
- Provide systematized acute trauma care.

**POPULATION HEALTH, RESEARCH, AND POLICY**
- Participate in and advocate for inclusive trauma systems.
- Direct and advocate for rapid, competent emergency medical services response.
- Lead efforts in policy development, implementation, and evaluation.
- Lead efforts in educating high-risk groups.
- Lead efforts to address and modify the environment to reduce risk of injury.
- Collaborate in multidisciplinary research to reduce injury risk and to improve care.

Injury Epidemiology and Documentation

Accurate data are essential to understanding the characteristics of a disease—its endemic populations, cyclic variations, geographic characteristics, and effectiveness of interventions. Consistent and comprehensive data should be gathered across the population of injured patients. Data can then be used for hypothesis testing, hypothesis generation, ongoing monitoring of disease patterns and characteristics, and understanding of outcomes of interventions.

Until recently, injury data were mostly limited to mortality data collected by coroners and medical examiners. For example, the Fatal Analysis Reporting System, a comprehensive data set on all car collision deaths in the United States, was established by the NHTSA in 1975 to examine the epidemiology of MVCs. Because death is uncommon compared with the large number of people injured, conclusions based solely on mortality data are limited. The advent of trauma center registries in the 1980s increased the availability of data. Because these data are skewed toward the most severe injuries, the conclusions based on these data are still limited when generalized to all injured people. Most injured patients (almost 90%) are treated and discharged from the ED. Many of these patients experience significant morbidity and incur significant cost to society.

One of the most important data elements for understanding injury is the E code, which is documented in the medical record. The E code is a system for identifying the cause of injury according to the International Classification of Diseases, Clinical Modification, and allows for systematic tracking of harmful agents. Several states have mandated documentation of E codes for all emergency department discharges; however, the completeness of this documentation is variable due to incompletely documented patient records.

E-coded hospital records can provide the who, what, and when of injury. Hospital records can help identify high-risk geographic areas for targeted prevention and intervention measures. However,
best practice would incorporate a comprehensive multiagency approach. Location of injury data may be available from emergency medical services (EMS), police, local government, and trauma registries. Statewide injury data linkages exist in some states and are available for surveillance information and research for unintentional and intentional injuries. For example, the Crash Outcome Data Evaluation System uses probabilistic linkage to create a database of police, hospital, EMS, and ED information for MVCs.

Investigators in Wales have demonstrated the effectiveness of a collaborative approach. After discovering that only 50% of assaults presenting to their ED in the city of Cardiff matched police records, the Cardiff Violence Prevention Group worked to reconcile future missing assault data. ED staff collected information on location of assaults, sharing raw anonymous data with local police on a monthly basis. Information was used to target violence prevention strategies in high-risk areas of the city, and violence rates over 5 years fell by almost one-third, compared to a rise of almost two-thirds in 14 similar cities. This was recently validated in another English community, and efforts to implement this program in the United States are ongoing.

Location data are also likely to be useful for environmental modification through engineering enhancements, police enforcement, or hazard removal. Linkage of these records to patient visits for specific research studies or surveillance is the next step in gaining a comprehensive understanding of the epidemiology of injury. Computer-based geographic information systems can be used to study injury locations with minimal training and resources, identifying areas with injury clusters for focused prevention efforts.

**Risk Assessment**

Ascertaining the forces released on the patient during a blunt injury (eg, car collision, fall) or penetrating injury (eg, gunshot, stabbing) leads to a directed approach to injury management. Extensive research has been done with crash dummies, mathematical models, and computer models to understand the mechanical forces applied in injury and human impact tolerance. Whether more accurate information regarding energy transfer (eg, actual kinetics of the collision from an on-board vehicle monitoring system vs. a first responder estimate of passenger space intrusion) will inform clinical decision making remains unclear.

Injury occurs when energy is delivered to the host in levels that exceed tissue and organ tolerance. This energy can be expressed in g-force. For example, the g-force that results from a MVC can be expressed by the following formula:

\[ g = \frac{\Delta v^2}{(\text{stopping distance} \times k)} \]

where \( \Delta v \) is the change in velocity, stopping distance is the distance over which the change in velocity occurs, and \( k \) is a constant. The g-force is inversely related to stopping distance; doubling the stopping distance reduces the g-force by half, but halving it quadruples the force. Thus, less g-force is applied if a lower velocity reduction occurs—as in braking to slow the vehicle before impact—or the reduction occurs over increasing distance, a key focus of vehicle design that allows the vehicle to deform during a collision. This understanding has led to myriad engineering solutions, such as interior padding, collapsible steering columns, vehicle crumple zones, water barrel barriers at bridge abutments, and flexible guardrails. One of the best examples of this principle is vehicle air bags, which result in increased occupant stopping distance during a collision and were credited with saving nearly 40,000 lives by 2013.

With any new safety countermeasure, there may be unintended consequences. First-generation air bags deploy with tremendous force at speeds of 140 to 200 mph. Such forces can be lethal to children in the front passenger seat, especially when unrestrained by safety belts, or when seated in rear-facing infant seats. A new generation of advanced, less forceful air bags has been in use since the late 1990s to reduce air bag–associated injuries.

**Motor Vehicle Collisions**

MVCs are the leading cause of death for children older than 24 months in the United States (see Table e2.1). Giving patients the necessary data for them to make an accurate self-assessment about their risks is the essence of patient behavioral interventions. When feasible, these messages should be part of every injured patient’s encounter with the health care system. The three behavioral risk factors most likely to result in motor vehicle injuries are speeding, seat belt nonuse, and driving after drinking alcohol. Unfortunately, alcohol-impaired driving remains a challenge; in 2013, there were over 10,000 MVC fatalities involving a driver with a blood alcohol level of 0.08 or higher, representing over 30% of the total traffic fatalities for the year.

Primarily due to increased seat belt use, motor vehicle fatality rates have declined by almost one-third, with fewer than 11 deaths/100,000 population between 2000 and 2012. Seat belt use in 2016 was at 90%, up from 70% in 2000. Proper use of lap and shoulder belts reduces the risk of death and severe injury to front seat passengers by 50%. In 2012, 50% of occupant MVC fatalities involved individuals who were not restrained. Proper restraint use in vehicles by occupants aged 5 years and older saved over 10,000 lives between 1975 and 2012. Almost all states now have primary or secondary laws, although states with primary laws have seat belt use 11% higher than those with secondary laws. New Hampshire has neither a primary nor secondary law.

In recent years, driver distraction, especially by device use for talking or texting, has been recognized as a significant hazard. The NHTSA reported that in 2011, 10% of fatal collisions and 17% of injury collisions were associated with distractions. National efforts continue to address this growing problem. For commercial truck and bus drivers, the US Department of Transportation banned texting in 2010 and all hand-held cell phone use in 2011. For noncommercial drivers, 44 states and Washington DC banned texting, and 14 states and Washington DC prohibit hand-held cell phone usage for drivers of all ages.

Age-appropriate child restraints reduce the risk of pediatric death in a MVC by 50%. Every pediatric visit is an opportunity to counsel parents on the safe transport of their children. In March 2011, the NHTSA revised its recommendations, stating that anyone younger than 13 years should ride only in the rear seat of a vehicle. Infant seats should never be positioned in the front seat within range of the air bag, and federal rules allow for air bags to be disabled if there are circumstances necessitating that small children ride in the front seat. Increasingly, vehicles are equipped with sensors that turn off the airbag when certain weight thresholds are not met.

US collision data have shown that the odds of injury is over five times greater for children younger than 24 months who are restrained forward-facing as compared to those who are rear-facing. These data have prompted the American Academy of Pediatrics to strongly recommend keeping children younger than 24 months rear-facing. The NHTSA recommends that infants 12 months and younger should always ride in a rear-facing car seat, and children 1 to 3 years of age should ride rear-facing until they outgrow the car seat manufacturer’s specifications. At this point, they should be placed in a forward-facing seat until they are 7 years of age or outgrow the car seat manufacturer’s specifications. A booster seat should be used until children are 12 years old or big enough to fit in a seat belt properly. For a seat belt to fit properly, the lap belt must lie snugly across the upper thighs.
and not compress the abdomen; the shoulder belt should lie snugly across the shoulder and chest, avoiding the neck and face. Proper seat belt position is important for all ages. Although seatbelt use has saved hundreds of thousands of lives, seat belts can also be a source of injuries, particularly when they are not positioned appropriately. For example, wearing only a lap belt or having too much slack in the seatbelt can result in the body jackknifing over the belt, causing abdominal injuries, fractures, and dislocations. Alternatively, when automatic “passive” shoulder belts that require manual fastening of the lap portion were put on the market, people frequently did not fasten the lap portion of the belt. In a collision, this resulted in submarining of the torso under the shoulder belt, increasing the risk of liver, spleen, and lung injuries. Although these types of seat belts have been discontinued, older model cars with this feature are still in circulation. Emergency clinicians should advise patients (particularly those of small stature) about the need to sit with at least 10 inches between the sternum and an air bag. For more information on automobile safety, visit www.safercar.gov.

Behavioral and Comorbid Risk Factors

Recognition of patients at high risk of injury affords opportunity for intervention. Risk factors for all types of injury include male gender, low income, illicit drug involvement, previous arrest, and young age. Injury in children is a marker of increased risk for future injury. Emergency clinicians should identify risks of future injury and opportunities for intervention. A brief review of the incident may help providers and parents identify risks for future injury and opportunities for intervention. An ED visit represents a teachable moment, when patients are aware of the consequences of their actions, to counsel patients about high risk behaviors. Although these lessons can be reinforced by primary care providers, impact wanes as the time from injury passes. Risk factors for intentional injury are complex and involve behavioral, social, and environmental factors. A history of prior significant, violence-related injury is a strong predictor of injury recidivism. EDs should have protocols in place for the detection, reporting, and referral of patients likely to be victims of future injury, including victims of domestic violence and intentionally injured children.

Hospital-Based Violence Intervention Programs

Up to 40% of violently injured youth aged 15 to 24 years will return to the ED for violence-related injuries; up to 20% will be victims of homicide within 5 years, a mortality rate greatly exceeding that of many cancers in that age group. Youth 14 to 24 years of age presenting to an ED with assault-related injuries are twice as likely to return for a violent injury and twice as likely to die within 24 months when compared to those with nonassault injuries. Hospital-based violence intervention programs reduce the risk of future injury, as well as recidivism to the criminal justice system. Effective programs couple the teachable moment with culturally competent outreach workers who continue to case-manage and mentor youth as outpatients. The National Network of Hospital-Based Violence Programs is now an international network, providing collaborative education, research, best practices, advocacy, and resources for hospital-based violence intervention programs (http://nnhvin.org).

Brief Emergency Department Interventions

The American College of Surgeons Committee on Trauma has recommended that all trauma centers screen for alcohol and provide interventions as a part of routine trauma care. Alcohol-related collision injury is a national epidemic in the United States, with over 30% of all motor vehicle traffic fatalities involving an alcohol-impaired driver. Patients with alcohol use disorders (AUDs) have higher rates of illness and MVC injury than the rest of the population, and patients with an AUD are more likely to drive after drinking. Reductions in alcohol-related deaths as a result of more stringent laws, public vigilance, and a societal shift toward the condemnation of driving while impaired have reduced impaired driving by social drinkers, but have not had significant effects on those with an AUD. Emergency clinicians have a unique role to play in the identification of high-risk patients. In particular, patients with AUD should be detected and referred for formal evaluation and treatment. A structured approach to detect and treat the disease should be brief and effective if it is to be used in a busy ED. Screening and brief intervention techniques have been validated in the ED, but likely require booster sessions after discharge.

Specific Issues and Disorders

Acute Care

The acute care component of injury control involves trauma system planning, medical direction of out-of-hospital care, and provision of systematized resuscitative care after the injury. Local resources for management of the injured patient should be identified. To avoid secondary injury from delays in transfer or inappropriate care, algorithms and agreements to transfer severely injured patients to the highest level trauma center available should be established. EMS providers should recognize higher risk trauma patients and select the most appropriate destination. For trauma centers, in-hospital triage criteria should be developed to align services and avoid unneeded overuse of trauma surgery teams.

An inclusive trauma care system uses all acute care and rehabilitation facilities that treat injured patients. In an inclusive system, even patients remote from trauma centers are integrated into the system, and every hospital can play a role based on available resources, whether it is the expeditious transfer of patients to comprehensive major (level 1) trauma centers or the treatment of patients without subspecialist needs. Treatment at a level 1 trauma center can improve survival for severely injured trauma patients by 25%.

Out-of-hospital emergency care can be an integral part of injury control. EMS response, triage, and treatment are the first steps in injury control, and triage protocols should avoid unnecessary delays in definitive care. The Field Triage Decision Scheme, first developed by the American College of Surgeons and updated in collaboration with the CDC, is intended to help EMS providers identify patients who need the resources of a trauma center. However, studies have consistently demonstrated that field triage protocols have a sensitivity less than 90% for identifying major trauma patients. EMS providers can also be involved in primary injury prevention through injury risk identification, documentation of injury data, and safety education programs.

Firearm-Related Injuries

Firearm injuries are a major US public health issue, with over 30,000 deaths and over 180,000 nonfatal injuries annually. In 2015, eight health organizations, including the American College of Emergency Physicians and the American Bar Association, published a position statement on firearm-related injuries in which they endorsed “universal background checks of gun purchasers, elimination of physician ‘gag laws,’ restricting the manufacture and sale of military-style assault weapons and large-capacity magazines by civilians, and research to support strategies for reducing firearm-related injuries and deaths.”
Emergency clinicians are at the front line of gun-related tragedies and have an obligation to educate their community on evidence-based risks of gun ownership. The United States has, by far, the highest private gun ownership rate of any developed or developing country, with 89 private guns/100 people (eg, compared to the United Kingdom, at 6 private guns/100 people). Risk of death by firearm is associated with rates of gun ownership. Gun deaths are 40 times higher in the United States than in the UK (10 vs. 0.25 annual deaths/100,000 population, respectively). A systematic review and meta-analysis of studies has evaluated the impact of gun access on suicide and homicide victimization. Access to guns increased the odds of suicide by more than three-fold and doubled the risk of being a victim of homicide. Recent mass shooting have given a false impression of the association of gun-related deaths and mental illness. In fact, the attributable risk of violence associated with mental illness has been found to be only 4%. The vast majority of patients with mental illness are never violent, and the vast majority of people who commit gun-related homicides have never been diagnosed with a major mental health disorder. Patients with depression are at increased risk of suicide, and those with access to firearms are more likely to die from suicide, irrespective of mechanism of death.

Emergency Medicine Leadership: Advocacy of Public Policy

As witnesses to daily preventable tragedies, emergency clinicians are uniquely qualified to advocate for effective measures to reduce injury rates. Most public health regulations and safety laws are under the jurisdiction of state legislatures and local governments. State and local policy makers are generally accessible to local physicians and other providers, who can provide expertise and advice on cost-effective, evidence-based injury prevention strategies. The American College of Emergency Physicians and National Association of EMS Physicians work on the national level to advocate for laws that will improve health and safety.

CHAPTER e2: QUESTIONS & ANSWERS

e2.1. What percentage of injured patients seen in an emergency department are treated and discharged rather than admitted?
   A. 59%
   B. 65%
   C. 76%
   D. 88%
   E. 98%

Answer: D. Approximately 88% of injured patients seeking medical care for injury are treated and discharged from the emergency department.

e2.2. What is the E code?
   A. A system for identifying the cause of injury in a patient's medical record
   B. A system for identifying the severity of injury in a patient's medical record
   C. A system for indicating the type of injury in a patient's medical record
   D. A system for predicting morbidity secondary to trauma in a patient's medical record
   E. A system for predicting mortality secondary to trauma in a patient's medical record

Answer: A. The most crucial data element for the understanding of injury is the E code, a system for identifying the cause of injury in a patient’s medical record, according to a classification published in the *International Classification of Diseases*. The “E” stands for external cause of injury, such as a motor vehicle collision, fall, or bicycle collision.

e2.3. Alcohol-related motor vehicle collisions account for what percentage of motor vehicle collision fatalities?
   A. 7%
   B. 19%
   C. 31%
   D. 68%
   E. 87%

Answer: C. Alcohol-related collision injury is a national epidemic in the United States, accounting for 31% of all motor vehicle collision fatalities.

e2.4. What percentage of violent injuries can be attributed to patients with a major mental health diagnosis?
   A. 4%
   B. 24%
   C. 44%
   D. 84%

Answer: A. Only 4% of violent injuries are attributed to people with a major mental health diagnosis. The vast majority of patients with mental illness will never be violent.

**KEY CONCEPTS**

- A humanitarian emergency, or humanitarian crisis, is a critical threat to the health, safety, security, or well-being of a community or other large group of people, usually over a wide area.
- Demand for humanitarian responders is likely to rise in the future as global urbanization and an increase in climate-related disasters conspire to create more frequent and severe disasters. At the same time, the growing professionalization of humanitarian aid will move the field closer to a model of international standards and cooperation among relief agencies.
- Humanitarian responders should understand the organizational strengths and weakness of the nongovernmental organization (NGO) and the setting, mission, and likely hazards associated with the deployment.
- Emergency clinicians have a skill set well suited for humanitarian response. Those who seek appropriate training and experience will have the opportunity to expand their professional practice while providing an essential service to the world’s most vulnerable populations.

Global and Humanitarian Emergency Medicine

Stephanie Kayden | Shawn M. D’Andrea

---

**Principles**

When a natural disaster or armed conflict forces thousands of people from their homes, a humanitarian emergency arises that requires a global response. Increasingly, emergency clinicians are called on to provide medical and organizational assistance in these humanitarian crises. Emergency clinicians contribute a unique skill set to the humanitarian environment, including an understanding of multiple medical specialties and expertise in managing within complex systems. Emergency clinicians have taken leadership roles in major humanitarian organizations, United Nations (UN) agencies, and national governmental disaster agencies. This chapter will provide an overview of global humanitarian emergencies and the role of the emergency clinician in humanitarian responses.

**Specific Types of Humanitarian Emergencies**

A humanitarian emergency, or humanitarian crisis, is “a critical threat to the health, safety, security, or well-being of a community or other large group of people, usually over a wide area.”

Humanitarian crises can be natural disasters (e.g., floods, earthquakes, tsunamis), human-made disasters (e.g., armed conflict, industrial accidents), or complex emergencies. A complex emergency occurs “where there is total or considerable breakdown of authority resulting from internal or external conflict and which requires an international response.” A key feature of humanitarian crises is the mass displacement of large numbers of people from their homes. Displaced populations are designated as internally displaced persons (IDPs) or refugees. An IDP is someone who has been forced from his or her home but who remains within the country of origin. If an IDP crosses an international border to seek help in another country, she or he becomes a refugee. The distinction is important. Whereas refugees enjoy protections and rights guaranteed by international treaty, IDPs must depend—in the absence of international aid—on their own government for help, even though the actions, or inaction, of their government may have caused their displacement.

Another feature of humanitarian emergencies is the threat of excess mortality. Conflict, disaster, and displacement can lead to a lack of food, water, healthcare, and sanitation. A humanitarian crisis emerges when this lack of basic human needs leads to (or threatens) a mortality rate greater than twice the baseline and requires emergency measures to prevent excess death and disability.

Most of the disease burden in humanitarian emergencies is brought on by the displacement itself. Removed from their usual sources of medical care, displaced people suffer complications of untreated hypertension, diabetes, and other diseases. Women and young infants die from the lack of safe perinatal care. Infants and children may not receive lifesaving vaccinations. Densely packed refugee camps promote outbreaks of measles and other infectious diseases. Erosion of public health programs, proper sanitation, and the lack of clean water, latrines, washing facilities, proper shelter, and good nutrition are often the main causes of poor health among displaced people.

**Natural Disasters**

Natural disasters, often seen as random acts of nature, attract media attention and public sympathy that spur a robust aid response. The risk for and effects of natural disasters, however, are predictable, and the type of medical response needed varies by the type of disaster (Table e3.1). Damage to health facilities is common to human-made and natural disasters, and medical relief is often focused on immediate emergency stabilization and reestablishing primary care and basic health services. Different types of natural disasters have specific effects on the health care system. Some disasters disproportionately affect the public health infrastructure (e.g., floods), whereas other types of disasters (e.g., earthquakes) damage the curative health care system and hospitals.

Earthquakes cause uniquely high rates of complex injuries—fractures, crush injuries, burns, and even hypothermia. Search and rescue teams are designated to manage confined space injuries and emergent field amputations. Surgical field hospitals are often needed in the first hours and days after an earthquake to provide lifesaving neurosurgical or orthopedic care when the local medical system is overwhelmed with trauma cases. The need for inpatient postoperative wound care, rehabilitation services, and prosthetic care continues for months or even years. Rebuilding hospitals is a top priority. A rapid transition to capacity building of the health care system is important, even as relief organizations and foreign medical teams begin to provide initial services after an earthquake.

In contrast to earthquakes, most natural disasters produce less severe, more easily survivable injuries. Humanitarian efforts after floods, hurricanes and other weather-related events usually focus on restoring baseline health services. Surgical field hospitals, if needed at all, typically perform wound care and everyday emergency surgeries (e.g., cesarean section, appendectomy). In disasters that produce high death rates—earthquakes, tsunamis, landslides, and volcanic eruptions—postmortem services may be needed emergently. Psychological first aid and mental health care are also vital to the population’s health and are integral to the health response to sudden-onset natural disasters.

Unlike sudden-onset natural disasters, droughts develop slowly over months or years. Lack of water leads to crop shortages, skyrocketing food prices, and disruption of food markets. Poor or isolated populations can suffer a lack of access to food that if unchecked, leads to famine. Thus, acute medical needs in a drought often stem from severe malnutrition, especially in young children, and subsequent infections. Medical responses to acute and chronic malnutrition are complex and specialized. Special
training in therapeutic feeding programs and supplemental food distribution is needed for emergency clinicians responding to famine or to any emergency in which a population's baseline rate of severe malnutrition is high.

### Armed Conflict

Armed conflicts are a major contributor to global humanitarian crises. The changing nature of conflict, including the growth of intrastate wars and asymmetric warfare, have led to mass displacement of populations and growing civilian mortality due to war. Moreover, natural disasters sometimes occur in a setting of underlying armed conflict. For example, people in Aceh, Indonesia, were already coping with an ongoing insurgency when the 2004 Indian Ocean tsunami struck.

The primary driver of a population's medical needs in armed conflicts is not violent injury but rather, as in natural disasters, displacement from usual sources of medical care, home, and household income. People fleeing conflict lose access to clean water, food markets, and health clinics, making them vulnerable to injury and disease. For example, people living with chronic mild malnutrition who are driven from their household fields and wells can quickly develop severe malnutrition, suffer from infections, and die. When conflict disrupts basic health services, untreated acute illnesses and acute exacerbations of chronic illnesses lead to increased morbidity and mortality.

As in natural disasters, the medical response during armed conflicts focuses on providing basic health services. Unlike in most natural disasters, however, armed conflicts also tend to cause a prolonged breakdown in local security, political, and civil society structures, which can inhibit the restoration of health services and permanently displace large populations. Responders must prepare for insecure environments and prolonged deployments. Violent injuries are typically limited to civilians who are trapped in active conflict zones or directly targeted by fighting forces. The number of civilians who suffer violent injuries is usually small in proportion to the total number of people displaced by armed conflicts. Nevertheless, survivors of war wounds, building collapse, and sexual violence will require high-level medical care and culturally appropriate mental health services.

### Disease Epidemics

Despite the experience of the 2014 outbreak of Ebola virus disease in West Africa, epidemics that result in humanitarian emergencies are rare, largely because most outbreaks of highly infectious, quickly fatal diseases such as Ebola have not typically spread beyond the rural areas where response agencies could contain them. Nevertheless, the 2014 West Africa Ebola outbreak caused over 11,000 deaths and highlighted the need for more international aid agencies to be able to respond to large global epidemics. In addition to the catastrophic death toll of the virus itself, its impact on fragile national health systems, including hospital and clinic closures and the death or flight of medical professionals, led to a surge in untreated illness and avoidable deaths. Weak public health infrastructure allowed the unchecked spread of the Ebola virus in Guinea, Liberia, and Sierra Leone. This rapid spread was in contrast to containment of the virus in countries with more developed public health systems, such as Spain, Nigeria, and the United States. Future epidemics, especially those that spread to densely populated areas with an underdeveloped public health infrastructure, may require an international medical relief and health care development response.

Epidemics of infectious diseases more commonly complicate, rather than cause, humanitarian crises. This was the case after the 2010 earthquake that struck Port-au-Prince, Haiti, devastating that country’s already weak health system. Ten months later after the earthquake, a cholera outbreak further strained health resources, increasing cholera transmission to displaced and nondisplaced populations and disrupting efforts to rebuild the health infrastructure damaged by the earthquake.

### Standards in Humanitarian Response

The variability in relief services in response to several recent humanitarian crises has led to a growing recognition of the value of standards in humanitarian aid. The international response community has developed practice guidelines that stem from research, international law, and expert consensus. These guidelines promote a standardized approach to improve the quality and efficiency of humanitarian aid. Responders should be familiar with these international laws and standards to ensure that their response efforts fulfill the rights of the people they are trying to help.

### International Law

Humanitarian aid is the attempt to respect the rights to assistance that all civilians have during humanitarian crises. To fulfill these rights, responders must know what they are. Two bodies of international law set forth the rights of people in humanitarian crises, international humanitarian law (IHL) and human rights law.

IHL is often described as the law of war, and its core documents are the Geneva Conventions. IHL gives special protections to people not taking part in conflict—civilians and soldiers rendered incapable of fighting due to injury, illness, surrender, or having been taken prisoner. It mandates that these noncombatants be treated humanely and be given food, water, shelter, and medical care. IHL not only ensures noncombatants the right to humanitarian assistance, but also grants humanitarian aid workers the right to offer that assistance. This means that humanitarian responders must be allowed to provide lifesaving aid uninterrupted and must not become war targets as long as they remain neutral in the conflict. Indeed, IHL is one of the primary tools used to ensure protection in conflict zones for aid workers who, as neutral actors, do not carry weapons. Humanitarian aid agencies often use IHL to negotiate with conflict commanders for safe access to civilian populations. Military leaders who do not respect the tenets of IHL can be individually prosecuted for IHL violations or war crimes.

Although IHL applies only during conflict, human rights law applies at all times. The 1948 Universal Declaration of Human Rights, the core document of human rights law, stated that “all human beings are born free and equal in dignity and rights” and are entitled to life, liberty, security of person, and “a standard of living adequate for... health and well-being.” The Declaration and other human rights laws enshrine specific civil, political, economic, social, and cultural rights, prohibit torture, genocide, and racial discrimination, and provide special protections for women, children, refugees, and internally displaced persons.

IHL and human rights law govern the scope of activity of humanitarian response. More importantly, it is by virtue of these international laws that humanitarian responders legitimately can enter a sovereign country and intervene in the lives of its citizens.

Humanitarian Principles and Codes of Conduct

The four humanitarian principles—humanity, neutrality, impartiality, and independence—are the bedrock of humanitarian action. Table e3.2 provides definitions of these principles, to which all humanitarian responders must adhere. Violations of the humanitarian principles can impede access to affected populations and create security risks for aid workers.

Nongovernmental organizations (NGOs) use codes of conduct to specify behavioral, professional, interpersonal, and ethical standards for their personnel. The most widely used code of conduct is the one in Box e3.1, prepared by the International Federation of Red Cross and Red Crescent Societies and International Committee of the Red Cross for disaster responders. Humanitarian response often requires long work hours in uncomfortable and insecure settings. Personnel must maintain appropriate conduct despite working in a high-stress setting. Maladaptive coping behaviors such as drug and alcohol abuse, inappropriate relations with national staff or locals staff, and security protocol violations put individuals and organizations at risk. Codes of conduct help establish behaviors necessary to ensure an ethical and effective response. Responders should be aware of, and abide by, the codes of conduct for their individual organizations.

### Sphere Standards

The Sphere Handbook, a collaborative project of humanitarian response experts, sets international standards for the provision of humanitarian aid. It is widely considered the “bible” of global humanitarian response. The Sphere Handbook begins with the Humanitarian Charter, which distills international law, humanitarian principles, and the humanitarian code of conduct into a five-page document that establishes the legal and ethical essence of the humanitarian imperative.

The Sphere Handbook provides minimum response standards for water and sanitation, food and nutrition, shelter, health care, and protection. It also sets forth certain core standards that apply to all sectors, such as involving beneficiaries in the response. These minimum standards are supplemented by specific indicators.

### Code of Conduct for the International Red Cross and Red Crescent Movement and Nongovernmental Organizations (NGOs) in Disaster Relief

1. The humanitarian imperative comes first.
2. Aid is given regardless of the race, creed, or nationality of the recipients and without adverse distinction of any kind.
3. Aid priorities are calculated on the basis of need alone.
4. Aid will not be used to further a particular political or religious standpoint.
5. We shall endeavor not to act as instruments of government foreign policy.
6. We shall respect culture and custom.
7. We shall attempt to build disaster response on local capacities.
8. Ways shall be found to involve program beneficiaries in the management of relief aid.
9. Relief aid must strive to reduce future vulnerabilities to disaster as well as meeting basic needs.
10. We hold ourselves accountable to both those we seek to assist and those from whom we accept resources.
11. In our information, publicity and advertising activities, we shall recognize disaster victims as dignified humans, not hopeless objects.
numerical sign posts that help responders know when they are on track to meet the standards. For example, the first Sphere standard for water supply is that “all people have safe and equitable access to a sufficient quantity of water for drinking, cooking, and personal and domestic hygiene.” But how much water is that? Although the exact answer may vary depending on the context, the key indicator for this standard is at least 15 L of clean water per person per day. Similar standards and indicators are given for other sectors of humanitarian aid. Box e3.2 highlights a few of the key indicators from the Sphere Handbook.

The Sphere Handbook provides a single set of uniform standards for aid agencies to follow in humanitarian response. The Sphere standards are the key measures whereby aid agencies evaluate their responses and, as such, are the basis of accountability for international response efforts.

Priorities in Global Humanitarian Emergencies

The goal of humanitarian response is to save lives, restore livelihoods, and rebuild communities. Effective humanitarian response centers around several key priorities.

**BOX e3.2**

Examples of Sphere Handbook Indicators of Minimum Standards

**WATER, SANITATION, AND HYGIENE**
- 15 L of water/person/day
- 250 people/water tap
- 10–20 L capacity water container for storage/household
- One toilet/20 people
- Toilets no more than 50 m from dwellings

**FOOD SECURITY AND NUTRITION**
- 2100 kcal/person/day
- 10% of total energy from protein
- 17% of total energy from fat
- Adequate micronutrient intake
- >90% of people aged 6–59 mo live within 1 day’s walk of a supplemental feeding program site

**SHELTER, SETTLEMENT, AND NON-FOOD ITEMS**
- 3.5 m²/person of covered living space in shelters
- 45 m²/person of total area of displacement camp
- 30-m firebreak between every 300 m of built-up area in camps
- Fuel-efficient stoves with required supply of fuel or domestic energy used by affected population

**HEALTH**
- One doctor/50,000 people
- One nurse/10,000 people
- One midwife/10,000 people
- One basic health unit (health post)/10,000 people
- One health care center/50,000 people
- One district or rural hospital/250,000 people
- >10 inpatient and maternity beds/100,000 people
- <1 death/10,000 people/day, or less than double the baseline crude mortality rate
- Under 5-yr-old mortality rate less than double the baseline

When measles vaccination coverage is <90% or unknown, conduct a mass measles vaccination campaign for children aged 6 mo–15 y.

**Protection**

The first priority—before food, water, shelter, or medical care—is the protection of people caught in the crisis. The humanitarian protection principles are outlined in the Sphere Handbook as follows:

1. Avoid exposing people to further harm as a result of your actions.
2. Ensure people’s access to impartial assistance—in proportion to need and without discrimination.
3. Protect people from physical and psychological harm arising from violence and coercion.
4. Assist people to claim their rights, access available remedies and recover from the effects of abuse.

The Sphere Handbook provides detailed guidance to help aid agencies adhere to these principles. Some protection measures are simple (eg, fences around refugee camps in insecure areas, good lighting near latrines); others are more complex (eg, issuing identification cards so that refugees can claim benefits, tracking unaccompanied children to help reunite families). Without adequate protection, other response measures may fail.

**Rapid Assessment**

A rapid assessment should always be conducted before large-scale aid operations begin. Taking time for an assessment may seem counterintuitive in times of urgent need, but rapid assessments are critical to ensuring that the right aid arrives in the right amount at the right time. Aid funds are always limited, and rapid assessments help avoid wasted resources. Most initial rapid assessments focus on needs over all response sectors, but some target specific areas such as health or shelter. Responders in the acute phase should be familiar enough with humanitarian aid to be able to participate in a multisector rapid assessment.

A rapid assessment takes from a few hours to a few days. Even in large-scale disasters, initial rapid assessments are complete by the end of the first week. Information gathered in a rapid assessment is shared with responding agencies to identify aid priorities and vulnerable populations. Priorities in different communities will vary, depending on the nature of the emergency. For example, flood waters may destroy homes in one community and food stores in another. Only after a rapid assessment can appropriate resources be mobilized to the neediest populations.

**Food, Water, and Shelter**

The major sectors of humanitarian response are water and sanitation, food, shelter, and health care. Although specific interventions will depend on the findings of the rapid assessment, most emergencies will require a response in each of these sectors.

Clean water, latrines, and washing facilities are among the most important public health measures in emergencies. If forced to choose, prioritize the provision of water quantity over quality. Lack of water causes people to stop washing, and poor hygiene is a major cause of disease in overcrowded refugee camps. Sanitation facilities must be provided to prevent fecal cross-contamination. Defecation fields, separated by gender, can be used until there is time to dig proper latrines.

Food distributions are necessary when food markets are disrupted and should be culturally appropriate, equitable, and organized. Nutritionally balanced dry rations of staple foods (eg, flour, beans, oil) are typically provided, but wet rations of prepared meals can be used if people cannot cook for themselves. Supplemental rations are given to pregnant and breast-feeding women, children, and sick or malnourished people. When local markets are functioning, allocations of cash or vouchers often replace food distributions.
Emergency shelter can be provided by housing displaced people with local host families, in vacant apartments, or—as a last resort—in tented camps. Careful camp planning is needed to reduce the impact of displaced populations on local communities and the environment, because camps can typically last not for weeks or months, but years or decades.

Health Care

Health care in humanitarian emergencies focuses on primary and preventive care, control of communicable diseases, and rehabilitation of basic health services. Control of communicable disease and public health surveillance are two key interventions in displaced groups living in densely populated camps and who often have low baseline vaccination rates. The biggest killers of children are respiratory infections and diarrheal illness. In endemic regions, malaria is also a dominant infectious disease threat. Measles is a particular threat in undernourished populations that have not been appropriately immunized. Measles vaccination campaigns for children are often the first medical priority after disasters.

Most humanitarian emergencies do not require large numbers of foreign surgical teams. The utility for foreign surgical teams may be in the care of war wounded, but they are most likely deployed to compensate for chronic shortages of surgical services. When surgical teams are needed, they should be trained in emergency obstetric care in addition to general surgery. In disasters that produce complex surgical needs, such as earthquakes, surgical field hospitals can be deployed to address acute injuries. Less recognized, however, is the need for postsurgical follow-up care and rehabilitation services. After the 2010 earthquake in Haiti, for example, some foreign surgical teams arrived to perform amputations or place external fixators for complex fractures, but left Haiti without establishing solid plans for rehabilitation or follow-up care. Surgical field hospitals must plan in advance to provide inpatient wound care and physical therapy for 3 to 6 months after surgery to patients whose homes and local health services have been destroyed. Amputees requiring prosthetics may need to be followed for years. Surgical responders have a responsibility to ensure, singlehandedly or through agency partnerships, comprehensive postoperative care to all patients.

Transition and Exit

The decision to respond to a crisis is much simpler than knowing how and when to end the relief effort.

- When is a humanitarian crisis over?
- How should deployed services be removed from an area chronically lacking resources?

Withdrawing relief aid may leave gaps in medical care, employment for local workers, and support for local livelihoods. Rather than abruptly pulling out, a successful relief effort will transition many activities from the relief phase to the development phase. Planning for this transition and exit must start early in the response and often will require collaboration with other agencies.

International Actors in a Humanitarian Response

The government of a country affected by a humanitarian emergency or refugee crisis has the primary responsibility to provide aid. If that government cannot or does not respond sufficiently, the international community may offer assistance. If the government invites this assistance, a variety of government organizations and NGOs, often collectively referred to as humanitarian actors, will arrive to provide relief. Responders should understand the roles of the major humanitarian actors—response organizations, the UN, government funding agencies, and those in the military—in funding, coordinating, and carrying out the response.

Response Organizations: The International Humanitarian Architecture

Among international responders, NGOs do most of the actual aid provision. Humanitarian emergency clinicians typically work with these groups. NGOs sometimes have access to vulnerable populations that are off limits to government agencies, and thus play a critical role in a humanitarian response. Although many international NGOs offer a range of response services, some are known for expertise in certain sectors. Doctors Without Borders (Médecins Sans Frontières), for example, is known for its specialized medical care, the International Rescue Committee for refugee health, and Oxfam for food and water expertise.21

The International Committee of the Red Cross (ICRC) and International Federation of Red Cross and Red Crescent Societies also represent response organizations; however, the two groups have very different mandates. Founded in Switzerland in 1863, the ICRC is in fact neither a governmental organization nor NGO. Instead, the ICRC is a neutral body mandated by the international community to aid and protect civilians in violent emergencies under the tenets of international humanitarian law. The ICRC provides health care, water and sanitation support, and international legal advocacy for refugees and IDPs.22 In contrast, the International Federation of Red Cross and Red Crescent Societies is comprised of 189 National Societies of the Red Cross and Red Crescent. The National Societies primarily work to support emergency preparedness and response in their own countries. A few of the National Societies, including the American Red Cross and Turkish Red Crescent, in coordination with the International Federation of Red Cross and Red Crescent Societies, also assist in emergencies outside their home countries.23

Despite the prominence of international groups in humanitarian emergencies, it is important to remember that most humanitarian aid comes from local sources—neighbors, community organizations, religious groups, and local government agencies. When international aid agencies arrive, they often partner with local community organizations that know the area well and have preexisting relationships with the people. This allows the international agency to provide efficient aid while helping to train and strengthen local organizations.

United Nations

The UN’s primary role in humanitarian crises is to create policies, set policies, and coordinate the international response. The UN Office for the Coordination of Humanitarian Affairs (OCHA) is the agency that serves as the main coordinating body for humanitarian crises. OCHA leads the cluster approach (see later, “Coordination of Global Humanitarian Response”), which coordinates local and international humanitarian actors in each sector of the field response. Some UN agencies also provide services directly to disaster survivors or NGOs in the field. For example, the World Food Program, which feeds more than 80 million people in 75 countries, provides logistic support for the transport and warehousing of NGO relief goods and food rations.

Foreign Governments

Although many aid agencies raise funds from private donors, the vast majority of funding for global humanitarian responses comes from foreign governments. Government funding agencies, such as the US Agency for International Development (USAID) or United Kingdom’s Department for International Development, often send representatives to the field to assess the scale of the emergency
Public Health and Humanitarian Emergencies

and to offer assistance. These foreign government funds—a total of US $16.4 billion worldwide in 2013—go to the local government of the affected country, to the UN, or to NGOs to fund specific aid proposals. USAID, via its Office of US Foreign Disaster Assistance, also guides the use of US military forces in humanitarian response missions.

Militaries

International militaries increasingly are engaged in humanitarian activities. Although militaries can offer a range of services, the main gap they fill is in large-scale transport and logistic support. Unlike most NGOs, militaries can rebuild bridges, reopen damaged airports, and/or transport equipment by helicopter. The militaries of the US, Canada, Israel, and United Kingdom are common responders worldwide, typically working with the military of the local government. A government dictates the actions of its military in accordance with its national interest and may decide to respond to some crises but not others.

The services of foreign militaries may be offered to nations that are responding to natural disasters to provide rapid logistic support. Military humanitarian response may also be deployed within peace-building operations to promote stability and reconstruction. In the setting in which militaries are engaged in conflict and humanitarian action, the lines between military action and humanitarian action may be blurred. Militaries may not always be perceived as neutral parties by beneficiaries, and NGOs that work with militaries risk a similar perception. This loss of perceived neutrality may cause NGOs to be threatened or attacked, even in other countries far from the disaster. NGOs who partner with militaries must therefore work to ensure an accurate perception of their neutrality.

Individual Responders

Given the complex nature of humanitarian emergencies, there is little place for individual responders without the support of a well-established agency. Most lone responders arrive ill equipped to be truly self-sufficient, and ultimately siphon scarce resources (e.g., lodging, food and water, ground transportation) away from the response. For this and many other reasons, individuals should not respond independently to humanitarian emergencies unless they do so as part of an experienced humanitarian relief organization. Would-be responders who cannot join an international NGO they do so as part of an experienced humanitarian relief organization. Would-be responders who cannot join an international NGO and must therefore work to ensure an accurate perception of their neutrality.

Role of the Emergency Clinician

Many people assume that humanitarian emergency clinicians spend most of their time treating trauma or serious injuries—fractures and crush injuries from earthquakes, infected flesh wounds in floods, or blast and penetrating injuries in conflict. Although this is true in some emergencies, the reality is that most of the time spent by an international medical responder is used to reinforce primary care and basic medical services that have been destroyed or bolster public health programs to prevent diseases in displaced populations.

Coordination of Humanitarian Response

Humanitarian relief can seem haphazard to the casual observer. In reality, global humanitarian response is carefully coordinated by the UN Cluster Approach, or cluster system, which is activated in large-scale international emergencies. Professional humanitarians are trained to coordinate with other NGOs via the cluster system to avoid duplication, omission, and inefficiency of humanitarian aid.

United Nations Cluster Approach

The cluster system was implemented in 2005 to increase coordination and accountability in relief aid. It is designed to accompany and advise, not supplant, the host government in its coordination of international response efforts. The cluster system divides humanitarian response into 11 sectors, or clusters (Fig. e3.1): camp management, early recovery, education, emergency telecommunications, food security, health, logistics, nutrition, protection, shelter, and water, sanitation, and hygiene.

Each cluster is overseen by a UN agency or other response organization termed the cluster lead, which fills this role in every response; the World Health Organization (WHO) is always the health cluster lead. Cluster leads gather and share information, promote adherence to international standards, coordinate NGO activities, and report progress to OCHA. OCHA, led in the field by the Humanitarian Coordinator, is responsible for overall coordination among the clusters and with the larger international community. Cluster meetings, held daily in the early response and less frequently over time, are the mainstays of coordination. They are often co-led by representatives of the host government (perhaps the Minister of Health in health cluster meetings) and the cluster lead agency (WHO). Representatives from NGOs, government agencies, and other groups working in the sector attend cluster meetings to share information and plan next steps.

Ongoing Coordination

Between emergencies, the 11 clusters work together on an ongoing basis to improve future responses. These global clusters are standing bodies that work to improve response preparedness, disseminate best practices, and support in-country clusters during disasters. Leaders of the global clusters report to the UN Under-Secretary General for Humanitarian Affairs and Emergency Response Coordinator, who also leads the Inter-Agency Standing Committee (IASC). The IASC brings together UN agencies, NGOs, ICRC and International Federation of Red Cross and Red Crescent Societies, World Bank, and International Organization for Migration to set policies and guidelines for effective humanitarian aid.

Emergency Clinician in Humanitarian Emergencies

Emergency clinicians are well suited for humanitarian response. They are comfortable working in stressful, chaotic environments. They can nimbly rearrange priorities and see the big picture in an ever-changing situation. They have uniquely broad medical skills that are useful in emergency response.

However, not all emergency clinicians make good humanitarian responders. They must consider whether relief work is right for them and be willing to seek training in the public health aspects of humanitarian response. Emergency clinicians should also be careful to choose an experienced aid agency with which to deploy.

Preparing for Humanitarian Response

Humanitarian response can be life-changing, usually for the better, sometimes for the worse. Humanitarian crises are stressful and unpredictable. To ensure an effective rewarding experience,
have deployed abroad to understand that adjusting to normal activities of work and life after returning from mission may be challenging. After the deployment, you may find it difficult to readjust to the ED. Some emergency clinicians become frustrated with patients with minor complaints after witnessing so much suffering abroad. Remember that these feelings are common.

Training for Humanitarian Response

Emergency clinicians should carefully consider whether they are properly prepared for humanitarian work.

Work in a humanitarian crisis often involves long hours, unfamiliar cultures, and uncomfortable accommodations. Electricity, running water, and mobile phone and Internet service may be unavailable. Insecure environments may require curfews and restriction to the NGO compound. Emergency clinicians who are new to austere living conditions might try backpacking in a low-income country before deploying to a humanitarian emergency.

The ability to cope with prolonged stress and personal discomfort is key. In a humanitarian response, toxic coping mechanisms (e.g., drugs, alcohol, sex) can endanger you and your team. Music, journaling, movies, and exercise are better ways to relax. You will be living in close quarters with your teammates for weeks or months and should make every effort to keep morale high and conflicts to a minimum.

Medical resources are often limited in the field. It can be useful to review certain procedures that are more common in austere medical environments (e.g., regional blocks instead of procedural sedation). It is also useful to provide on-site educational support which servicing abroad.

Humanitarian deployments can be a challenge for your personal relationships. It is important for emergency clinicians who have deployed abroad to understand that adjusting to normal activities of work and life after returning from mission may be challenging. After the deployment, you may find it difficult to readjust to the ED. Some emergency clinicians become frustrated with patients with minor complaints after witnessing so much suffering abroad. Remember that these feelings are common.

Training for Humanitarian Response

Emergency clinicians are expected to be familiar with a large and growing body of literature, guidelines, and procedures. Emergency clinicians considering humanitarian work should seek additional training. Formal educational opportunities include humanitarian certification courses, fellowships, and graduate degrees. Certification courses in humanitarian aid are available through a number of universities and organizations. The Humanitarian Academy at Harvard and Tufts University offer nondegree courses in humanitarian assistance. International organizations also offer courses. The ICRC’s Health Emergencies in Large Populations (HELP) course is taught in several locations around the world. Lasting a few days to a few weeks, certification courses can be a most effective way to prepare for a deployment or explore a career in humanitarian aid.
Humanitarian crises are often set in dangerous and insecure environments, with inadequate public safety and medical facilities. Responders should understand and adhere to their organization’s safety protocols, even if the advice seems overcautious. Mandatory seat belt use, for example, helps prevent harm from the most common cause of unintentional injury to aid workers—road traffic accidents. Responders must be familiar with the basic tenets of personal security and travel safety to prepare for deployment in the field.

Unfortunately, attacks on humanitarian aid workers have increased in the past decade. Modern conflicts often directly target civilians and aid workers, and hostage ransoms are an increasingly important source of revenue for some non–state–armed actors. Responders should be aware of how their own identity or the reputation of their NGO affects their level of risk. Although it is extremely unlikely that any single aid worker will be a victim of violence, responders should review insurance policies before deployment to an insecure area. Health, life, and disability policies, particularly if provided by your home hospital, may not cover death or injury while working in a humanitarian crisis. Responders can improve their awareness of field security via training programs such as the UN Department of Safety and Security Field Course (online).

**Ethical Dilemmas**

Humanitarian emergency clinicians often face ethical dilemmas in the field that would never occur at home. At home, triage usually decides who gets care first; in a humanitarian crisis, triage often decides who gets care at all. This unfamiliar territory can lead emergency clinicians into ethical pitfalls in humanitarian medicine. A common pitfall is deciding to work outside of one’s scope of clinical practice because of an incomplete understanding of referral capability. Nonsurgeons may attempt a makeshift emergency appendectomy, rationalizing that this care is “better than nothing.” In our experience, this emergency clinician is usually unaware of surgical resources a few hours (or minutes) away. Even in disasters, humanitarian emergency clinicians have a responsibility to arrange a referral and transport system for patients needing higher care. In the few cases when referral is truly impossible, the patient and family must be fully informed of your lack of experience and given the option to refuse.

Many ethical dilemmas are better addressed by a group. Group consensus, especially when beneficiaries are represented, helps avoid war zone decision making and removes the burden of an emotional decision made by an individual. Having a standard protocol for the use of prearranged ethics groups will allow for quick decisions.

**What to Bring**

First-time responders often wonder which items are most useful to pack for humanitarian work. Overpacking can mean leaving things behind in an emergency evacuation, when luggage is often restricted to a 12-kg carry-on. Box e3.4 provides suggestions for packing light while remembering the essentials.
### Packing List for Humanitarian Deployments

#### DOCUMENTS
- Passport (plus copy)
- Visa (plus copy)
- Immunization card (plus copy)
- Air ticket (plus copy)
- Letter of invitation by NGO
- Medical evacuation insurance card (plus copy)
- Health insurance card
- Trip cancellation insurance
- Driver’s license (consider an international driver’s license)
- ATM/credit cards (may not work)
- Cash (generally U.S. currency, but check with contacts)
- Copy of medical school diploma
- Copy of medical license
- CV/résumé
- Hospital identification badge
- Business cards
- Extra passport photos
- Address and contact list

#### ADDRESS AND CONTACT LIST
- Field supervisor and local contacts
- Arrival and airport contacts
- Local embassy
- Family, friends
- Lost ATM, credit card reporting contacts
- Medical evacuation company
- Health insurance company
- Local airline office
- Travel agent

#### GEAR
- Money belt
- Day pack
- Alarm clock (that runs on batteries)
- Headlamps, flashlights
- Mosquito net
- Sunglasses
- Sleep sack
- Rain protection
- Duct tape
- Swiss Army knife (not for carry-on)
- Sewing kit
- Ear plugs
- Pocket tissues (toilet paper)
- Baby wipes
- Luggage locks (for hotel, not flight)
- Quick-dry travel towel
- Flip-flops, shower sandals
- Bandana, scarf
- Travel clothesline
- Laundry detergent
- Sink stopper
- Ziploc bags
- Water purifier or disinfection tablets
- Phrasebook
- Travel guide
- Stethoscope
- White coat, surgical scrubs (where applicable)
- Pocket medical references

#### ELECTRONICS
- Laptop and power cord
- Electrical adapters, converter

#### FIRST-AID KIT
- Sunscreen
- Mosquito repellent
- Antimalarial prophylaxis
- HIV postexposure prophylaxis
- Alcohol-based hand sanitizer
- Traveler’s diarrhea antibiotic(s)
- Antidiarrheal
- Laxative
- Acetaminophen, ibuprofen
- Decongestant
- Antihistamine
- Albuterol inhaler
- Prednisone
- Fluconazole
- Bacitracin ointment
- Antiemetic
- Vitamins
- Oral contraceptive, emergency contraceptive
- Condoms
- Adhesive bandages
- Blister dressings
- Alcohol wipes
- Cloth tape
- Wound closure strips
- Safety pins
- Tweezers
- Spare eyeglasses, contact lenses
- Sutures and needle driver
- Nitrile gloves

#### TOILETRIES
- Toothbrush, toothpaste
- Dental floss
- Shampoo, soap
- Comb, brush
- Razor, shaving cream
- Deodorant
- Contact lens kit
- Eyeglasses (and spare)
- Sunscreen
- Makeup
- Mirror
- Lotions, creams
- Lip balm
- Tampons
- Facecloth
- Prescription medicines

#### EXTRAS
- Notebook, journal, pens
- Gum, candy, protein bars
- Instant coffee packages, teabags
- Magazines, novels
- Playing cards, games
- Textbooks, equipment donations
- Gifts for hosts

---

*In carry-on bag.

NGO, Nongovernmental organization.
KEY CONCEPTS

- A humanitarian emergency, or humanitarian crisis, is a critical threat to the health, safety, security, or well-being of a community or other large group of people, usually over a wide area.
- Demand for humanitarian responders is likely to rise in the future as global urbanization and an increase in climate-related disasters conspire to create more frequent and severe disasters. At the same time, the growing professionalization of humanitarian aid will move the field closer to a model of international standards and cooperation among relief agencies.
- Humanitarian responders should understand the organizational strengths and weaknesses of the nongovernmental organization (NGO) and the setting, mission, and likely hazards associated with the deployment.
- Emergency clinicians have a skill set well suited for humanitarian response. Those who seek appropriate training and experience will have the opportunity to expand their professional practice while providing an essential service to the world’s most vulnerable populations.

CHAPTER e3: QUESTIONS & ANSWERS

e3.1. A health crisis exists in a refugee population when the crude mortality rate (CMR) reaches how many times the baseline CMR?

A. 1.5  
B. 2.0  
C. 3.0  
D. 5.0  

Answer: B

e3.2. Which of the following medical responses is the highest priority in a nation with an underdeveloped health care infrastructure after a natural disaster causing mass population displacement into temporary shelters?

A. Immediate construction of temporary hospitals with surgical capability  
B. Implementation of hand hygiene education programs  
C. Rapid deployment of emergency surgical teams  
D. Rapid initiation of measles vaccination campaign

Answer: C
e3.4. For what activities should emergency clinicians deploying to a humanitarian crisis generally be expected to prepare?

A. Assist in the care of a large number of emergency surgical patients.
B. Gain experience practicing outside of one's usual scope of practice.
C. Provide care for a large number of chronically malnourished patients.
D. Provide mostly primary care and assist in restoration of basic health services.

Answer: D

Medical Team Operations in Urban Search and Rescue

Medical Team Tasks

Confined Space Rescue

Specific Medical Challenges

KEY CONCEPTS

- Tactical emergency medical support (TEMS) facilitates the overall success and safety of law enforcement missions during all phases of a tactical operation through the delivery of preventive, urgent, and emergency medical care.
- A fundamental principal in tactical medicine is that the medical mission may be subordinate to the overall law enforcement mission.
- Tactical combat casualty care (TCCC) has adapted civilian advanced life support principles to provide medical care during an effective hostile force encounter. Its goals are to treat the casualty, prevent additional casualties, and complete the mission.
- TCCC is divided into three phases of care—care under fire (CUF), tactical field care (TFC), and combat casualty evacuation care (CASEVAC).
- Tactical emergency casualty care (TECC) addresses casualty management during high-threat civilian tactical and rescue operations and is divided into three phases; direct threat, indirect threat, and evacuation care.
- Urban search and rescue (USAR) is the science of responding to, locating, reaching, medically treating, and safely extricating victims entrapped by collapsed structures. The primary role of the emergency clinician is support of the health and welfare of the team members, including canines.
- USAR teams often treat crush syndrome, particulate inhalation, hazardous materials exposures, and blast injuries.
- In crush syndrome, treatment with fluids begins prior to extrication to avoid life-threatening complications once the patient is extricated.
CHAPTER e4
Tactical Emergency Medical Support and Urban Search and Rescue

PRINCIPLES

Background

A confluence of domestic incidents in the mid-1960s of unprecedented violence and scale demonstrated to law enforcement agencies in the United States that increased preparedness and specialized response teams were necessary. Today, law enforcement agencies in the United States have ready access to highly trained individuals and special equipment to respond to high risk, operationally complex situations. Often referred to as special weapons and tactics (SWAT), police tactical teams respond to rapidly evolving patterns of crime and violence, including the criminal use of military style weapons, taking of hostages, and increasingly organized terrorist activities.

National leaders within law enforcement, emergency medicine, and emergency medical services (EMS) have supported the development of dedicated medical support for tactical teams. Position papers from the National Tactical Officers Association, National Association of EMS Physicians, and American College of Emergency Physicians supported tactical emergency medical support (TEMS) as an essential component of law enforcement teams, which help maintain a healthy and safer environment for law enforcement and the public. Today, the breadth of law enforcement tactical missions commonly includes hostage or barricade situations, high-risk warrant service, active shooter incidents, violent felon apprehension, civil disturbances, dignitary and executive protection, maritime and dive operations, and explosive ordnance disposal.

Tactical emergency medical support (TEMS) is now viewed as an invaluable adjunct to law enforcement operations and public safety. Professional practice in the area of TEMS continues to attain formal recognition, and physician competency is a newly established requirement of subspecialty certification in emergency medical services (EMS). Furthermore, the efficacy of tactically trained medical providers and their roles have been described in a growing number of unconventional prehospital scenarios.

Organizational Principles and Objectives

Tactical medicine augments high-risk law enforcement operations by providing scene commanders with medical threat assessments, delivering immediate emergency medical care, and promoting the safety and health of law enforcement personnel. Tactically trained medical personnel achieve their objectives through mission pre-planning, implementation of clinical practices developed specifically for law enforcement applications, and provision of a critical interface between law enforcement personnel, conventional EMS, and existing emergency health care system infrastructure.

The broad goals of TEMS are to facilitate the overall success and safety of law enforcement missions during all phases of a tactical operation through the delivery of preventive, urgent, and emergency medical care. The basic approaches used by tactical medicine providers were initially developed by the military for small unit operations and have been widely applied to civilian law enforcement. The primary function of TEMS during a mission is to provide broad medical support, including injury prevention, resource identification and allocation, and rapid access to emergency medical care.

During law enforcement operations, medical activities and casualty movements are a coordinated effort between the command post, operational team leaders, and medical support element. Tactical physicians are often on scene to ensure that local medical resources, including conventional EMS, are properly staged, briefed, and ready to assist the operation as circumstances require and safety permits. During law enforcement operations of extended duration, the need for dedicated medical support resources is intensified.

A fundamental principal in tactical medicine is that the medical mission may be subordinate to the overall law enforcement mission. In contrast to conventional EMS and hospital practices, in which the sole priority is usually the health and welfare of the patient, the essential priority in a tactical mission is the success of the law enforcement objective. When a casualty occurs during a tactical operation, medical providers may be directed to delay or modify medical care until the tactical commander determines that rendering care will not jeopardize the overall mission.

SPECIAL ISSUES

Tactical Emergency Medical Support Providers and Scopes of Practice

A fundamental consideration in TEMS concerns the level or type of medical provider to be deployed. Most commonly, tactical medical support is rendered by experienced emergency medical personnel with EMS backgrounds, trained in basic life support (BLS) or advanced life support (ALS). BLS providers are generally more plentiful, with fewer requirements for initial and continuous training, whereas ALS providers are typically less numerous, difficult to train, and more costly to maintain. Larger law enforcement agencies, especially at the federal and possibly state levels, may deploy BLS and ALS personnel. True multitiered programs in TEMS are rare, not accounting for the potential operational role of tactical physicians or the agency medical director.

Jurisdictional EMS standards may restrict many or all the interventions commonly found in the ALS scope of practice. Nevertheless, specialized BLS providers with focused expansions of practice have demonstrated real effectiveness in providing operational medical support for federal law enforcement. TEMS medical directors have the authority to train BLS providers
judiciously, with enhanced skill sets required for clinical care in the tactical environment.

Given that the overall volume of patient encounters in tactical emergency medical support is relatively low, TEMS-specific protocols and training paradigms have often been developed with a paucity of data and based on anecdotal evidence. Although the impetus for many tactical medicine programs was the threat of traumatic injuries during law enforcement special operations, opportunities to provide more comprehensive medical support beyond the narrow scope of trauma care have emerged. Subsequently, there has been increasing evidence to justify broadened medical training, protocols, and expanded clinical skills sets for tactical medics.6

Two distinct subgroups of encounters occur in TEMS—low-frequency, high-acuity (eg, gunshot wound, cardiac arrest, and falls from height) and high-frequency, low-acuity (eg, musculoskeletal sprains and strains, environmental exposures, lacerations).7 Management of low-frequency, high-acuity patient encounters requires proficiency in lifesaving interventions; however, advanced clinical skills are difficult to maintain in low-volume EMS systems. Furthermore, because TEMS providers typically serve as medics as well as law enforcement officers, resources, including time, funding, and opportunities to maintain clinical skills, are often limited.

By contrast, high-frequency, low-acuity patient encounters are not medically emergent or even urgent in many cases. However, because patient populations encountered in TEMS are very often law enforcement officers, the impact of these low-acuity issues on overall tactical team performance, capacity, or time can be significant. Unfortunately, the assessment and management of low-acuity medical complaints (eg, laceration repair, vaccination, muscle cramps) are often out of the scope of training and clinical practice of conventional EMS providers. The challenge for medical directors and law enforcement agencies is to ensure that protocols, training, and ultimately provider capabilities are sufficiently adept to manage types of clinical encounters in TEMS.

Medical Oversight of Tactical Emergency Medical Support

As a rapidly expanding subspecialty area of prehospital medical practice and law enforcement operations, TEMS programs carry special administrative and medical oversight requirements. Qualified physician leadership and medical control, as in conventional EMS, is an essential component of tactical emergency medical support. Unique qualifications and expanded responsibilities exist for medical directors. The ability to manage thoughtfully and proactively enhanced provider scopes of practice, adjuncts to conventional EMS interventions, and integration with existing health system and public safety infrastructure are equally important.

The successful integration of emergency medicine into law enforcement operations is a complex process that mandates effective medical leadership. All fundamental tenets of medical director accountability in EMS apply to tactical emergency medical support programs. The added challenges of directing care in the law enforcement arena and potential need for augmented capacities of TEMS providers call for additional qualifications of emergency clinicians directing such programs. Of foremost significance, the TEMS medical director must understand the central mission of the law enforcement agency. TEMS medical directors must formulate and implement clinical policies, protocols, and training sufficient for TEMS providers to deliver effective preventive, urgent, and emergent medical care in the dynamic law enforcement environment. Additionally, they must be proficient in the formulation of operational medical plans and have a functional understanding of special operations and tactical procedures.

**Casualty Care**

Tactical combat casualty care (TCCC) originated as a project within naval special warfare, and tactically appropriate battlefield trauma care guidelines were published in 1996. These were later continued by the US Special Operations Command and used today throughout the Department of Defense. TCCC adapted civilian ALS principles to provide medical care during an effective hostile force encounter. These combat trauma care guidelines combine advanced trauma care with good small-unit tactics, balancing the need to treat casualties against the risks of providing such treatment within the context of an ongoing operation. The three major goals of TCCC are to treat the casualty, prevent additional casualties, and complete the mission.

The treatment principles of TCCC were developed based on the recognition that preventable deaths in combat scenarios occur from uncontrolled hemorrhage due to extremity wounds, tension pneumothorax, and airway compromise from maxillofacial trauma. TCCC recognizes that the tactical objective of neutralizing an effective hostile threat generally takes precedence over providing definitive medical care. TCCC divides the level of medical care provided during a hostile force encounter into three phases—care under fire (CUF), tactical field care (TFC), and combat casualty evacuation care (CASEVAC).

**Care Under Fire**

CUF is the first phase of casualty care that is rendered while tactical operators are under direct effective hostile fire (Fig. e4.1). CUF encourages the casualty to remain engaged in the operation, seeking cover and concealment, and returning fire, if possible. Immediate lifesaving maneuvers that may be rendered by a casualty (“self-aid) or a nearby tactical operator (buddy aid) are emphasized in this phase. Because uncontrolled hemorrhage from extremity wounds is a leading cause of preventable battlefield deaths, CUF emphasizes control of life-threatening bleeding with early use of a tourniquet. Airway management while under fire is preferentially deferred until the TFC phase. Both CPR and cervical

![Fig. e4.1. Care under fire—direct threat phase of care. (Courtesy Nelson Tang, with permission)](image-url)
spine immobilization are usually contraindicated in the presence of an ongoing hostile threat.

Tactical Field Care

TFC begins once operators, who remain at risk of injury, are no longer under direct effective hostile fire and is most often rendered by trained medical providers. Assessment and treatment priorities include assessing the casualty for unrecognized hemorrhage and controlling all sources of bleeding, including through the use of tourniquets and topical hemostatic agents (Fig. e4.2). Attention is directed toward establishing or maintaining an unobstructed airway by using simple maneuvers, such as inserting a nasopharyngeal airway and/or placing the casualty in a recovery position. Casualties with unilateral blunt or penetrating chest trauma in respiratory distress are rapidly evaluated for tension pneumothorax or sucking chest wounds and undergo needle decompression, if indicated, or are treated with an occlusive dressing, as necessary. When possible, intravenous (IV) or intraosseous access is established to administer fluids and/or medications. Grossly contaminated wounds, open fractures, or penetrating abdominal trauma may receive empirical IV antibiotics, especially if evacuation and transport times are prolonged. The need to perform a complete physical examination (secondary survey) is balanced against the risk of hypothermia, which should be actively managed using layered coverings and warmed IV fluids.

Combat Casualty Evacuation Care

CASEVAC is the care rendered while the casualty is being evacuated by ambulance or helicopter to undergo definitive care at a prestaged landing zone or casualty collection point (Fig. e4.3). Interventions and therapeutics during the CASEVAC phase most closely approximates conventional EMS care and includes continued ALS while en route to receiving facilities, most often trauma centers. The situational tempo, severity of specific injuries, numbers of casualties, and local system practices determine whether the TEMS provider accompanies an injured law enforcement officer to the hospital to act as the patient’s advocate, as well as a liaison to tactical command.

Committee for Tactical Emergency Casualty Care

Whereas TCCC is widely accepted in the military combat setting, there are some data that question the applicability of TCCC to the civilian environment. Recognizing this, a diverse group of first responder and tactical medicine experts, the Committee for Tactical Emergency Casualty Care was formed and, in May 2011, held their inaugural meeting to create the tactical emergency casualty care (TECC) guidelines, a set of best practice recommendations for casualty management during high-threat civilian tactical and rescue operations. Based on principles derived from TCCC, TECC guidelines consider differences in the civilian environment, including resources allocation, patient populations, and scopes of practice. TECC is applied in three phases—direct threat, indirect threat, and evacuation care.

Direct Threat Care. To meet the specific operational scenarios and terminology used in the civilian sector, the first phase of care under TECC is termed direct threat care. The priorities of direct threat care emphasize mitigating the threat, moving the wounded to an area of relative safety, and managing massive hemorrhage by using tourniquets. Additionally, emphasis is placed on the importance of various rescue and patient movement techniques, as well as rapid airway opening and positioning techniques, if operationally feasible. Treatment and operational requirements are the same for all levels of providers during this phase of care.

Indirect Threat Care. Indirect threat care can be initiated once the casualty is in a relatively safe area, with proper cover and less chance of rescuers being injured or patients sustaining additional injuries. Similar to TCCC, assessment and treatment priorities in this phase focus on the preventable causes of death. Four different levels of providers are assigned to scope of practice and skill sets based on level of training and certification—law enforcement officer, emergency medical responder (or equivalent), emergency medical technician (EMT), and advanced EMT-paramedic.

Evacuation Care. The final phase of care under TECC is called evacuation care, when the casualty is moved to a definitive treatment facility. Most additional interventions during this phase of care are similar to those performed during normal EMS operations. However, reassessment of prior interventions and hypothermia management are emphasized.

Tactical Team Health

Historically developed to address the well-recognized potential for lethal injuries intrinsic to tactical operations, the initial focus of TEMS was training and preparation to render lifesaving trauma care. Tactical medicine today is much broader in scope, drawing
are invoked, it is the responsibility of the TEMS medical director to ensure that advanced procedures and protocols are justified to support force protection and mission safety.36 Due to the special requirements for operating in the austere conditions of law enforcement SWAT missions, TEMS providers are usually small in number and logistically limited to the resources and medical oversight.37 TEMS programs are to support the overall success of the tactical mission by optimizing the health and wellness of the operational team as well as providing immediate emergency medical and trauma care. 

Core tactical medicine responsibilities include the health surveillance of law enforcement personnel and delivery of preventive and routine medical care. It is common today for TEMS providers to manage issues such as sleep–rest cycles, hydration and nutrition, vaccinations, environmental exposures, and preexisting medical conditions for the tactical teams. High-volume TEMS programs have demonstrated that tactical medics most frequently encounter law enforcement officers as patients, validating these programs as ones designed to protect the health and welfare of the team.38

Integration With Emergency Medical Services Infrastructure

TEMS programs generally operate within the framework of existing local EMS systems and abide by established mechanisms for administrative oversight. More often than not, TEMS may be a specialty function or service of the existing EMS system. Even if a law enforcement agency has intrinsic tactical medical assets and thereby jurisdictional authority to expand on established EMS protocols or scopes of practice, from quality and system-based perspectives, it is preferable for TEMS programs to operate in overall concert with the local infrastructure. Close working relationships contribute to quality of care and optimize transitions of care and mutual aid responses.

Although concepts of operational security (OPSEC) are basic to law enforcement and security personnel, they may be less familiar to EMS and other health care providers. OPSEC governs how sensitive information, even unclassified, is handled and protected. In the law enforcement context, there can be issues related to OPSEC that preclude full disclosure of all TEMS-related capabilities and activities in all cases. Nevertheless, focused outreach and effective communication on the part of the TEMS medical director can be tremendously valuable for system integration and interagency public safety cooperation.

EMS policies and protocols are typically administered at the state or regional level, thereby resulting in significant jurisdictional variation. In many cases, EMS protocols, provider certifications, duties, and scopes of practice are matters of legislative governance.39 Specific local protocols, including the provision of TEMS care, is often guided by factors such as population, geography, resources, and medical oversight.40 If expanded scopes of practice are invoked, it is the responsibility of the TEMS medical director to ensure that advanced procedures and protocols are justified to support force protection and mission safety.41

Due to the special requirements for operating in the austere tactical environment, TEMS providers are often trained and authorized to perform therapeutic procedures that may be unconventional when compared to standard EMS. Procedures such as supraglottic airways, needle thoracostomy, tourniquets, topical hemostatic agents, intraosseous vascular access, and field-expedient splinting and wound care are often deployed in TEMS for lifesaving care. Additionally, specialized capabilities such as medical threat assessment, remote patient assessment, forensics and evidence preservation, rapid decontamination, and hazardous materials management have all been described.

Active Shooter Incidents

The prevalence of hostile mass casualty events, such as school, workplace, and public venue shootings, seems to be an ever-increasing phenomenon worldwide. Determining potential strategies for prevention remains a massive undertaking for medicine and law enforcement alike. The destructive capacity of single or small numbers of individuals armed with conventional weapons is now well recognized and must be addressed using public safety and public health approaches.

Although ideally suited to function within the operationally austere conditions of law enforcement SWAT missions, TEMS remains a relatively small and selective component of the multidimensional response to a mass casualty, active shooter incident. Just as a SWAT team is not likely to be the first law enforcement element to arrive at such an incident, TEMS providers will generally not be the first medical responders on the scene. Additionally, TEMS providers are usually small in number and logistically embedded with the tactical team. Recent studies of active shooter events in the United States have characterized the brief duration of many such events, building consensus that first responders and conventional EMS must be capable of reaching casualties quicker and initiating lifesaving procedures sooner.17 Consensus panels have been convened to formulate best practices from military and civilian TEMS lessons learned.31,32,33 EMS systems have developed rescue task force models to enable its providers to respond to active hostile situations using personal protective equipment, with law enforcement officer providing security and deploying medical approaches adapted from TEMS principles.31,32

Future Directions

Despite rapidly growing recognition of its efficacy, the development of TEMS programs and capabilities remains a collateral responsibility for most law enforcement agencies around the country. TEMS programs often remain informal initiatives, existing under the auspices of ad hoc agreements between local law enforcement and a medical entity, with limited funding. Widespread medical acceptance of the TEMS mission and continued development of physician leadership remain as challenges.

URBAN SEARCH AND RESCUE

Urban search and rescue (USAR) is the science of responding to, locating, reaching, medically treating, and safely extricating victims entrapped by collapsed structures. USAR is a so-called multihazard discipline because it may be needed in a variety of emergencies, natural disasters such as earthquakes and hurricanes, and human-made disasters, including terrorist attacks, building and structure collapse, hazardous materials spills, and trench collapse.24 Federal activation of USAR teams occurs when local and state resources have been overwhelmed during a disaster and there has been a request from a state governor to the President for the activation of federal response assets. For responding teams to be effective, they should be highly trained, quickly deployable, mobile, and self-sufficient.

In the 1980s Fairfax County Fire and Rescue (Virginia) and Metro-Dade County Fire Department (Florida) created elite search and rescue teams. These teams worked with the Office of Foreign Disaster Assistance and were deployed to disaster scenes internationally. In 1989, the Federal Emergency Management Agency (FEMA) established the National Urban Search and Rescue Response System after recognizing that there was a lack of teams for urban disasters. The model structures local emergency rescue personnel into response task forces. In 1991, USAR was incorporated into the National Response Plan (NRP), which is organized into 15 emergency support functions (ESFs) grouped under Homeland Security. Search and Rescue Annex is ESF 9. Any of the ESFs can be used during a disaster.

Components and Structure of an Urban Search and Rescue Team

The responding team must mobilize quickly, without placing additional demands on the already stressed infrastructure at the
Coordination and cooperation with local resources and other teams is critical. Thus, the USAR team is integrated into the Incident Command System (ICS) at the disaster.

The search team is responsible for developing and implementing a plan to search the area for victims. The search team can be subdivided into two teams, a canine search team and technical search team. The canine team uses specially trained dogs to locate trapped victims. The technical team uses specialized microphones, listening devices, cameras, and fiberoptic devices to locate victims in confined spaces. The search team is responsible for locating victims and identifying probable areas where victims may be found.

The rescue team is composed of rescue specialists. Once a victim or potential victim is located, the rescue team is responsible for creating a safe entrance and exit from the victim’s position. The rescue team works with the technical team to shore and stabilize unstable walls.

An effective USAR team has properly trained personnel and appropriate equipment. The equipment cache allows the task force to be totally self-sufficient for the first 72 hours and be capable of 24-hour operations for 10 days. The FEMA equipment cache is divided into five groups—rescue, medical, technical, communications, and logistics equipment. The medical equipment cache was designed to treat the unique medical needs of entrapped victims, as well as the medical needs of the team itself. The medical cache contains enough supplies to handle 10 critical cases, 15 moderate cases, and 25 minor cases. The cost of an entire cache is approximately $2 million. Coordination and cooperation with local resources and other teams is critical. Thus, the USAR team is integrated into the Incident Command System (ICS) at the disaster.

The search team is responsible for developing and implementing a plan to search the area for victims. The search team can be subdivided into two teams, a canine search team and technical search team. The canine team uses specially trained dogs to locate trapped victims. The technical team uses specialized microphones, listening devices, cameras, and fiberoptic devices to locate victims in confined spaces. The search team is responsible for locating victims and identifying probable areas where victims may be found.

The rescue team is composed of rescue specialists. Once a victim or potential victim is located, the rescue team is responsible for creating a safe entrance and exit from the victim’s position. The rescue team works with the technical team to shore and stabilize unstable walls.

The technical team includes structural specialists, hazardous materials specialists, heavy rigging and equipment specialists, technical information specialists, and communications specialists, who work collaboratively to ensure a safe and efficient operation. The logistics team is responsible for all the equipment needs, including inventory, issuing, and record keeping. Finally, the medical component is composed of personnel who are responsible for the medical needs of the task force personnel and victims. Typically, medical personnel consist of paramedics and two emergency clinicians.
Medical Team Operations in Urban Search and Rescue

A number of unique considerations must be addressed for USAR. The emergency clinician on the team works with the team leader and managers of the other teams (eg, search, rescue). To do this efficiently, the emergency clinician should be familiar with the capabilities and training of all the members on the team and the ICS. Cross-training of team members is ideal, and team training sessions are required.24-26 Often during a disaster, the medical team will join the search and rescue teams.

USAR team emergency clinicians have two primary objectives during a search and rescue. The first is to care for the medical team members, who will often be working to stabilize trapped victims medically for prolonged periods of time. Often, the emergency clinician may also be at the patient’s side. The second objective is to provide medical care to other team members and canines. To prepare for this, USAR emergency clinicians participate in a weeklong training course, which includes drills in confined space and learning about medical scenarios that will likely be encountered during a USAR deployment (Fig. e4.5).

Medical Team Tasks

Predeployment

The function of the medical team in the predeployment phase is to ensure that the entire team is fit and functional for deployment and that the medical equipment cache is organized and up to date.25 The perceived medical threats in the deployed area must also be addressed (eg, endemic diseases, water contamination, insect threats, existing medical support), and medical intelligence information needs to be collected and addressed (Box e4.1). A plan is developed to transfer and transport victims and for fatality management.

Deployment

The medical action plan, which may include information regarding medical evacuation and local EMS resources, is critical for ensuring smooth operations and should be updated as conditions or knowledge changes.24-25 The medical team must also assess the adequacy of team members’ rest and sleep, as well as the psychological effects of the situation.24-25 In addition, the USAR medical assets must be integrated with the overall medical response that is guided under ESF 8, “Public Health and Medical Services.” This includes integration with existing medical resources, DMATs, TEMS resources, military resources, and public health. The medical team also undergoes basic veterinary training before deployment during their training.

Confined Space Rescue

A confined space is defined as any space with limited access and ventilation. The emergency clinician and medical team must be prepared to work in this setting and should be aware of issues related to team and victim safety, air purification, and structural dynamics related to collapse or impending collapse.26-27 Medical providers may be asked for input on cessation of rescue operations based on the likelihood of finding survivors. The decision should be based on individual characteristics of the event and not rely on predefined time frames, as evidenced from the 2010 Haitian earthquake.27

Specific Medical Challenges

USAR teams will typically respond to the aftermath of earthquakes, collapsed structures, terrorist bombings, hurricanes, and other natural and human-made disasters.27 Reviews of the literature have identified the types of medical problems and conditions that might be encountered.24,25 Most of the medical conditions are those encountered in the emergency department and are managed similarly. The following clinical problems occur with much greater frequency in the USAR environment: crush syndrome, compartment syndrome, particulate inhalation, hazardous materials exposures, and blast injuries.25

Crush Injury and Crush Syndrome

Crush syndrome is defined as the systemic manifestations caused by crushed muscle tissue. This typically occurs when blood flow

BOX e4.1

Predeployment Medical Intelligence Gathering

- Type of disaster and predicted numbers and types of potential victims
- Capabilities of team to deal with medical aspects of the situation, including dealing with injured team members
- Local emergency departments’ level of functioning; trauma center status and location
- Local EMS resources
- Location of planned triage staging area
- Communications with local resources (eg, EMS, police, emergency departments, fire and rescue)
- Weather, environment, or hazardous materials issues
- Availability of other resources (eg, military, NDMS, DMAT)

DMAT, Disaster medical assistance team; EMS, emergency medical services; NDMS, National Disaster Medical System.
is restored to the crushed tissue and toxins are released systemically. It is estimated that 3% to 20% of earthquake victims and up to 40% of survivors of multistory building collapses will have crush syndrome. Early hydration of the victim in the rubble before, during, and after extrication can mitigate the nephrotoxicity of crush syndrome. The amount of time required for crush syndrome to develop depends on the amount of pressure and patient factors. It can occur within 1 hour if the pressure is severe, but often takes 4 to 6 hours to develop.

The cause of muscle injury in crush injury is not fully understood and remains controversial. When the crushed area is released, there is a release of toxic intracellular contents into the systemic circulation. Victims may be trapped for days with a severe crush injury and appear stable when they are reached by rescuers, but deteriorate soon after being rescued. The major causes of early death due to crush syndrome are hypovolemia due to third spacing of fluid, dysrhythmias due to severe metabolic acidosis, and hyperkalemia. Delayed causes of death include renal failure, acute respiratory distress syndrome, sepsis, ischemic organ injury, disseminated intravascular coagulopathy, and electrolyte disturbances.

Early aggressive therapy is essential for the prevention of crush syndrome and should begin before extrication. All victims who have an obvious crush injury or are immobilized for 4 hours or more should be considered to have crush injury. The severity of the crush syndrome may be related to the number of extremities injured. In a Japanese study of earthquake victims, the incidence of acute renal failure due to crush syndrome was 50% for one, 75% for two, and 100% for three or more involved extremities. Once a victim is located, the medical component needs to be actively involved with the rescue process and treatment should be started before extrication. Continuous cardiac monitoring is recommended and can be performed in confined space. Hydration is started along with the usual management of hypokalemia (eg, insulin or glucose, ion exchange resins, β-agonists, ). Current FEMA guidelines recommend IV calcium only for arrhythmias or when there is documented severe hypocalcemia. An average-sized adult may require up to 12 L/day of fluids to sustain a forced diuresis of 8 L/day to prevent renal complications. Continued monitoring of the patient’s vital signs, hydration status, and urine output should be used to guide fluid administration.

Airway Management
Another unique medical problem in USAR is dust and airway contamination. During earthquakes and building collapses, a tremendous amount of dust is released into the air. During the first 48 hours of rescue efforts at the World Trade Center, 90% of the 10,116 New York City Fire Department rescue workers evaluated at the site reported an acute cough, often accompanied by nasal congestion, chest tightness, and/or chest burning, but only three required hospitalization for respiratory symptoms. A cough was eventually found in 1561 (29.1%) firefighters at baseline and 1186 (22.1%) at follow-up, including 559 with delayed onset.

The victim of a collapsed structure should be assumed to have some sort of dust contamination. Evaluation of the airway for any evidence of burns or hazardous materials exposure is routine. During the extrication process, patients are fitted with dust and particle masks, and their airway is monitored for deterioration. If intubation is considered, it should be done early, before edema obstructs the airway and prior to a prolonged extrication, when accessing the victim may be difficult.

Hazardous Materials and Exposures
Chemical, explosive, and radiologic agents represent potential threats to the USAR team. Hazardous materials may be released from many sources, such as manufacturing plants or transportation vehicles. Explosions and fires from disrupted gas lines or other flammable and explosive gases and liquids present significant hazards. Radiation is a danger that may threaten search and rescue operations, as demonstrated by the Fukushima nuclear reactor radiation leak after the earthquake in Japan in 2011.

Medical teams are integral to the success of the USAR capability. USAR deployments are often highly challenging, and the prerequisite training is rigorous. The USAR emergency clinician must be prepared and specifically trained to work in confined spaces and other challenging situations.

### KEY CONCEPTS

- **Tactical emergency medical support (TEMS)** facilitates the overall success and safety of law enforcement missions during all phases of a tactical operation through the delivery of preventive, urgent, and emergency medical care.
- A fundamental principal in tactical medicine is that the medical mission may be subordinate to the overall law enforcement mission.
- **Tactical combat casualty care (TCCC)** has adapted civilian advanced life support principles to provide medical care during an effective hostile force encounter. Its goals are to treat the casualty, prevent additional casualties, and complete the mission.
- TCCC is divided into three phases of care—care under fire (CUF), tactical field care (TFC), and combat casualty evacuation care (CASEVAC).
- **Tactical emergency casualty care (TECC)** addresses casualty management during high-threat civilian tactical and rescue operations and is divided into three phases: direct threat, indirect threat, and evacuation care.
- **Urban search and rescue (USAR)** is the science of responding to, locating, reaching, medically treating, and safely extricating victims entrapped by collapsed structures. The primary role of the emergency clinician is support of the health and welfare of the team members, including canines.
- USAR teams often treat crush syndrome, particulate inhalation, hazardous materials exposures, and blast injuries.
- In crush syndrome, treatment with fluids begins prior to extrication to avoid life-threatening complications once the patient is extricated.

CHAPTER e4: QUESTIONS & ANSWERS

e4.1. Which of the following is a priority for the tactical emergency medical support (TEMS) provider in caring for a victim shot during a hostage incident?
A. Bag-valve-mask ventilation
B. Cervical spine stabilization
C. Endotracheal intubation
D. Intravenous access and fluid resuscitation
E. Tourniquet application to bleeding extremity

Answer: E. This scenario describes care rendered by TEMS in the hot zone, or care under fire; thus, conventional care sequences do not apply. Priorities include mitigation of threats, tourniquet use for serious bleeding, and evacuation to a safer location.

e4.2. A 28-year-old man has been trapped under building debris for 6 hours following an urban explosion. A rescue team is actively working to extricate him. Both legs are pinned, but his torso is free. Which of the following statements is true?
A. Aggressive fluid therapy should begin after extraction.
B. Assessment for crush injury should occur after 2 hours of immobilization.
C. Cardiac monitoring is indicated during extrication.
D. Prophylactic calcium is indicated.
E. The incidence of acute renal failure is approximately 30%.

Answer: C. The incidence of crush injury rises dramatically after 4 hours of immobilization. Continuous cardiac monitoring is indicated during extrication. Calcium is indicated only for refractory arrhythmias or documented hypocalcemia. Fluid resuscitation may help prevent the hypotension associated with release of the entrapped limb(s) and should be initiated before extirpation. The incidence of acute renal failure is 50% with one-extremity and 75% with two-extremity crush injuries (Japanese earthquake victim data).

e4.3. The principles of TEMS have largely developed from which type of incidents?
A. Civilian multicasualty events
B. Military conflicts
C. Natural disasters
D. Pandemics

Answer: B. The principles of TEMS have largely developed from lessons learned during military conflicts and most closely emulate the medical support structure of military special operations units.

e4.4. Which of the following is incorrect with respect to the principles of tactical medicine?
A. During a tactical operation, TEMS providers may be directed to delay medical care.
B. During a tactical operation, medical care of a casualty may jeopardize the overall mission.
C. None of these.
D. The first priority is always the health and welfare of the patient.
E. The medical mission may be subordinate to the overall law enforcement mission.

Answer: E. A fundamental principal in tactical medicine is that the medical mission may be subordinate to the overall law enforcement mission. In contrast to conventional EMS and hospital practices, in which the sole priority is usually the health and...
welfare of the patient, the essential priority in a tactical mission is the success of the law enforcement objective. When a casualty occurs during a tactical operation, medical providers may be directed to delay or modify medical care until the tactical commander determines that rendering care will not jeopardize the overall mission.

e4.5. Which of the following is a primary responsibility of the USAR team emergency clinician?
   A. Extrication of victims
   B. Medical treatment of entrapped victims
   C. Locating victims
   D. Support the health and welfare of team members

Answer: D. The USAR team emergency clinician has a primary responsibility to the team members should they require medical attention.
Emergency Ultrasound*

Heidi Harbison Kimberly | Michael B. Stone

**KEY CONCEPTS**

- Emergency ultrasound is performed and interpreted by the emergency clinician at the bedside.
- Emergency ultrasound is designed to answer focused clinical questions.
- The key to proficiency in emergency ultrasound is practice.
- Credentialing guidelines exist to guide emergency clinicians in the acquisition of this important skill.
- All emergency clinicians should be familiar with the resuscitative applications of emergency ultrasound, including focused assessment with sonography for trauma (FAST), focused cardiac ultrasound, abdominal aortic aneurysm assessment, and procedural guidance for central venous catheter placement.
- The “four Is” of emergency ultrasound are as follows: (1) identification of appropriate patients for whom emergency ultrasound is likely to be valuable; (2) image acquisition; (3) interpretation of the acquired images; and (4) integration of the ultrasound findings into patient management.

CHAPTER e5

Emergency Ultrasound

Heidi Harbison Kimberly | Michael B. Stone

PRINCIPLES

Emergency ultrasound (US) is the simultaneous performance and interpretation of a focused sonographic examination at the bedside of the patient for the diagnosis, resuscitation, monitoring, guidance, and treatment of emergency medical conditions. Emergency US is, by definition, performed by the treating emergency clinician and consists of four essential components called the “four Is”: (1) identification of appropriate patients for whom US is likely to be valuable; (2) image acquisition; (3) interpretation of the acquired images; and (4) integration of the ultrasound findings into patient management.

Although the operator is typically an emergency clinician, he or she may be an emergency clinician assistant, nurse practitioner, or trained emergency nurse or paramedic—all under the supervision of a trained, credentialed emergency clinician. Emergency US is typically performed in the emergency department (ED) but may also be performed in other areas of the hospital, free-standing EDs, out-of-hospital mobile transport (ground and/or air transport), disaster scenes, military engagements, international rescue work, resource-limited rural and international settings, and remote locations (eg, space, sea, or land centers with limited or no medical access).

As illustrated by the four Is, the emergency clinician performing an emergency US examination selects patients, acquires and interprets images, and integrates their findings directly into clinical care. This is the fundamental difference from the paradigm of traditional imaging specialties, in which a trained technologist typically performs the examination and a physician subsequently interprets, or reads, the images.

Emergency US examinations are focused examinations of an area of the body, organ system, physiologic pattern, or goal-directed investigations of an emergency symptom or sign. Essentially, emergency US is designed to answer a focused, often dichotomous, clinical question (eg, “Does this young female patient with vaginal bleeding have an intrauterine pregnancy?” or “Is there a pericardial effusion present in this dyspneic oncology patient?”). As such, emergency US examinations are neither sufficient nor intended to diagnose all of the broad range of pathologic processes encountered in emergency medicine. Technical limitations clearly exist, whether related to clinician experience, skill or confidence, or a patient’s anatomic factors or pathologic condition. If the question of interest cannot be answered after an emergency US is performed, emergency clinicians should choose an alternative strategy to pursue a definitive answer. Despite its limitations, however, the main risk management issue associated with emergency US relates to failure to use this modality when it is available and appropriate.

HISTORY

A half-century of international scientific innovation resulted in the initial medical use of US in the 1950s by physicians interested in its advantages over traditional imaging, including noninvasiveness, lack of ionizing radiation, and superior resolution. In the 1980s, emergency clinicians started to use US as a way to rule out emergent, so-called silent diagnoses, such as ectopic pregnancy, intraperitoneal hemorrhage, hemopericardium, cholelithiasis, renal colic, and aortic aneurysm. A model curriculum was created by the Society for Academic Emergency Medicine (SAEM) that initiated formal guidance for emergency US programs. Due in part to resistance from traditional imaging specialties, the American College of Emergency Physicians (ACEP), passed a resolution that hospital credentialing committees follow specialty-specific guidelines for US-based credentialing.

Specialty-specific guidelines, created in 2001, updated in 2008 by ACEP, and endorsed by SAEM in 2010, specify emergency US scope of practice, primary applications, training pathways, number of procedures required for training before credentialing, quality assurance and documentation guidance, and training course outlines. Today, more than 95% of emergency medicine residency programs teach US, approximately 30% to 60% of community hospitals have instituted bedside US performed by emergency clinicians, and emergency ultrasound is an integral component of the 2013 model of the clinical practice of emergency medicine.

Since 2008, emergency US has been recognized by organizations outside emergency medicine, including the American Institute of Ultrasound in Medicine, with implementation of the focused assessment with sonography for trauma (FAST) examination. Emergency US training occurs throughout all levels of practice. Medical student emergency US training has been defined by national organizations and, increasingly, medical schools are incorporating emergency US education into their curricula. Emergency US is now one of the competency assessments required of emergency medicine residents by the Residency Review Committee for Emergency Medicine, with defined requirements as set by national organizations.

US fellowships have become the most common postgraduate emergency medicine fellowship and provide advanced training in emergency US. For emergency clinicians in practice who did not receive residency training in emergency US, initial training often occurs through continuing medical education courses, followed by a period of proctoring or supervision. Recent educational advances, such as simulation, task trainers, Internet-based training, and nontraditional media (eg, electronic books, mobile device applications, social media) may all enhance US training. As a result of the rapid proliferation of high-quality, nontraditional US educational materials, references to free online content (eg, websites, podcasts, videos) will be provided throughout this chapter, where appropriate.

TRAINING, CREDENTIALING, AND ACCREDITATION

Emergency US training occurs throughout all levels of practice. Medical student emergency US training has been defined by national organizations and, increasingly, medical schools are incorporating emergency US education into their curricula. Emergency US is now one of the competency assessments required of emergency medicine residents by the Residency Review Committee for Emergency Medicine, with defined requirements as set by national organizations.

US fellowships have become the most common postgraduate emergency medicine fellowship and provide advanced training in emergency US. For emergency clinicians in practice who did not receive residency training in emergency US, initial training often occurs through continuing medical education courses, followed by a period of proctoring or supervision. Recent educational advances, such as simulation, task trainers, Internet-based training, and nontraditional media (eg, electronic books, mobile device applications, social media) may all enhance US training. As a result of the rapid proliferation of high-quality, nontraditional US educational materials, references to free online content (eg, websites, podcasts, videos) will be provided throughout this chapter, where appropriate.
US programs typically require some investment in education and hardware, but reimbursement for professional and hospital fees is adequate to meet a return on investment within years, depending on the number and types of US, payer mix, and documentation.

Credentialing for emergency US at the hospital level is based on specialty-specific national guidelines. See the ACEP ultrasound website (https://www.acep.org/ultrasound) for helpful references for program development and education.

**APPLIED ULTRASOUND PHYSICS AND INSTRUMENTATION**

A brief summary of relevant terminology is presented in Box e5.1. Readers seeking more in-depth reviews of ultrasound physics, machine controls, ultrasound modes, and instrumentation are encouraged to visit the Sonoguide website (http://www.sonoguide.com/). Relevant lectures on this topic can be accessed through the Academy of Emergency Ultrasound (AEUS) website.

**EQUIPMENT AND SAFETY**

Modern broadband frequency transducers can selectively use several available US frequencies to maximize tissue penetration or image quality, depending on the application. Transducer design and footprints (the actual transducer surface area touching the patient) can be divided into three categories—flat linear array transducers, curved linear array transducers, and phased array transducers.

- Flat linear array (high-frequency) transducers generate a square or rectangular image with excellent lateral resolution at the expense of width of field and are used for superficial examinations (eg, soft tissue, musculoskeletal) and as procedural guidance for vascular access.
- Curved linear array (low-frequency) transducers, which generate a wider field of view at the expense of lateral resolution, are usually used for applications requiring deep tissue penetration, such as evaluation for pregnancy or abdominal aortic aneurysm. The endocavitary transducer is a highly curved linear array (high-frequency) transducer that is generally used for endovaginal evaluation.
- Phased array (low-frequency) transducers offer a smaller footprint than curved linear array transducers and are ideal for cardiac evaluations, although they can also be used for abdominal examinations. Transesophageal echocardiographic and biplanar transducers have more recently been used in EDs exploring new imaging venues.

US biosafety includes use of the ALARA (as low as reasonably achievable) principle, appropriate Doppler usage, and appropriate microbiologic disinfection of the ultrasound transducer and system. US is kinetic energy, and users of this technology should observe the ALARA principle by performing procedures only when indicated and limiting the time of sonographic investigation. Doppler modes should be minimized over sensitive tissue, including early gestation and germinal, mucosal, ocular, and neural tissues. Surface transducers should be cleaned at the bedside with mechanical removal of gel and debris, followed by disinfection with an appropriate spray or wipe. Endocavitary transducers require more prolonged and substantial cleaning. Safety also includes the use of appropriate barriers over transducers, including condoms, gloves, or commercial barriers over endocavitary transducers and sterile transducer covers for sterile procedures. For nonsterile procedures, or for examination of obviously infected or disrupted skin surfaces, an adhesive dressing can be applied to minimize contamination of the transducer.

**APPLICATIONS AND CATEGORIZATION**

In 1994, SAEM categorized US applications broadly into abdominal, cardiac, obstetric-gynecologic, and special applications. In 2001, ACEP developed guidelines that categorized applications more specifically to include trauma, pregnancy, abdominal aortic aneurysm, cardiac (for pericardial effusion and cardiac activity), biliary, renal, and procedural guidance. In 2008, ACEP added deep venous thrombosis (DVT), thoracic studies for pneumothorax and pleural effusion, soft tissue and musculoskeletal studies, and ocular examination as core applications. Advanced applications at that time included testicular, adnexal, bowel, advanced echocardiography, transesophageal echocardiography, transcranial Doppler, and contrast studies. Grouping of US applications into categories of resuscitative, diagnostic, symptom- or sign-based, procedural guidance, and monitoring and therapeutic helps describe the uses of US in emergency medicine.

The most common uses of emergency US include trauma, cardiac (eg, cardiac arrest, pericardial effusion), abdominal aortic aneurysm, pelvic, biliary, procedural, renal, and DVT. Emergency US is commonly used in clinical pathways or algorithms to identify or exclude emergency medical conditions rapidly. US guidance can also assist with the performance of percutaneous procedures, such as vascular access, diagnostic and/or therapeutic drainage (eg, thoracentesis, paracentesis, pericardiocentesis, arthrocentesis), lumbar puncture, abscess drainage, peripheral nerve blocks, foreign body localization and removal, airway management and others.

Common applications of emergency US are reviewed below, using the four Is approach to highlight critical components of specific examinations. Where available, links to open access educational content are provided for a more in-depth review of...
examination-specific issues related to image acquisition and interpretation.

**SPECIFIC ULTRASOUND USES**

**Trauma Ultrasound**

**Identification of Appropriate Patients**

The trauma US examination, also called the focused assessment with sonography for trauma (FAST) examination, was originally developed as a noninvasive alternative to diagnostic peritoneal lavage in the evaluation for hemoperitoneum. As such, the FAST examination is most appropriate for patients with blunt abdominal trauma with hemodynamic instability. The EFAST (extended FAST) examination also includes the evaluation for potential pneumothorax, hemothorax, and pericardial effusion, and often plays a valuable role in the evaluation of patients with blunt or penetrating thoracoabdominal trauma.

**Image Acquisition**

The FAST technique uses a low-frequency broadband transducer (2–6 MHz) to evaluate dependent peritoneal spaces, pleural spaces, and the pericardium. A thorough evaluation of the potential spaces in the right upper quadrant includes the hepatorenal space (Morison’s pouch), diaphragmatic space (including assessment of the thorax for pleural fluid and suprahepatic area for peritoneal fluid), and inferior edge of the liver and right kidney. In the left upper quadrant emergency clinicians should first evaluate the subdiaphragmatic space and tip of the spleen, because free intraperitoneal fluid tends to accumulate here before spilling over the splenorenal ligaments into the splenorenal space. The pelvis should be evaluated in the transverse and longitudinal planes, where fluid may be detected deep to the uterus (in females) or in the retrovesical space (in males). Emergency clinicians may choose to incorporate additional views of the paracolic gutters caudal to the upper quadrant views to detect free fluid surrounding the bowel. Pleural fluid is typically detected during the upper quadrant evaluations described above.

The most common cardiac FAST windows include subcostal (or subxiphoid) and parasternal windows (see below, “Cardiac Ultrasound”). Evaluation for pneumothorax typically uses a low-frequency transducer at a shallow depth or a high-frequency transducer, which provides better resolution, placed along the anterior and lateral chest wall.

**Interpretation of the Acquired Images**

Typically, fluid in the peritoneum, pericardium, and pleural cavity is anechoic, but it can have echogenicity if active extravasation, a blood clot, or bowel contents are present within the fluid. Compared with other fluid-filled structures in the abdomen and pelvis, peritoneal free fluid generally has sharp pointy edges and an irregular shape, whereas most visceral or vascular structures have intrinsically smooth oval or round contours, with less edge detail (Figs. e5.1, e5.2, and e5.3). The volume of fluid required for a positive US study depends on the site of injury, sonographic window, and experience of the operator, but 250 mL or more is generally visible, and nearly 600 mL of fluid is required for a positive upper quadrant window when fluid is infused from the pelvis.

Pericardial fluid is contained within the parietal and visceral pericardium. Once a certain volume is reached, the pressure in the pericardial space increases dramatically, resulting in cardiac tamponade. Generally, at least 50 mL of fluid is required to cause hemodynamic compromise in a patient without prior pericardial
Inflammation. Pleural fluid can also be detected using US, and assessment for hemothorax can be performed in the setting of blunt or penetrating trauma. US is an accurate modality for the evaluation of suspected traumatic pneumothorax through direct visualization of the sliding of the visceral and parietal pleural layers (see below, “Thoracic Ultrasound”).

Integration of Ultrasound Findings Into Patient Management

The test characteristics of the FAST examination vary greatly among published studies, and depend on operator skill, patient acuity, and choice of gold standard used for each study, with clinical endpoints suggesting higher accuracy. The FAST does not identify every peritoneal injury, although the need for intervention in undetected injuries has not been studied. The use of US during resuscitation has been shown to decrease patient morbidity, time to operating room, and hospital charges.

Patients with traumatic pericardial effusions diagnosed by emergency US receive more rapid operative intervention and have lower mortality rates. US can also diagnose pneumothorax with excellent sensitivity and specificity compared with supine chest radiography, with accuracy often approaching that of computed tomography (CT).

The FAST examination is accurate and clinically relevant in patients with penetrating thoracic injury and hypotensive patients with blunt abdominal trauma. In contrast, a stable blunt trauma patient with a positive FAST examination will often still require CT imaging due to the growing trend for nonoperative or interventional management of blunt solid organ injury. In addition, FAST is insufficiently sensitive to exclude injuries in stable blunt trauma patients or patients with purely anterior penetrating abdominal trauma to the abdomen.

In pediatric patients, the FAST is not only less accurate but will more often be positive in the pelvis than in the right upper quadrant. In obstetric patients, few observational studies have been performed demonstrating reasonable sensitivity and specificity, although abruptio and fetal viability may necessitate an earlier operative course.

FAST is unreliable for the detection of hemoperitoneum in patients with pelvic fractures, and the detection of free fluid in an unstable patient with a pelvic fracture may be due to uroperitoneum from bladder injury rather than hemoperitoneum from vascular injury, clouding the decision for laparotomy versus pelvic embolization. In addition, retroperitoneal injuries to the genitourinary tract are not reliably assessed with the FAST examination.

Additional online educational content relevant to trauma ultrasound can be accessed as follows:

- Emergency Ultrasonography website—video gallery

Pelvic Ultrasound

Identification of Appropriate Patients

Pelvic US by emergency clinicians is used to evaluate patients rapidly who are at risk for ectopic pregnancy.10 Ultrasonography is used to confirm intrauterine pregnancy in early pregnancy, which indirectly excludes ectopic pregnancy in most patients. Indications for sonographic evaluation of the first-trimester pregnant patient include symptoms or signs that suggest an ectopic pregnancy, molar pregnancy, or fetal demise and dating of the pregnancy. Emergency US may also facilitate detection of fetal viability, incomplete abortion, ectopic pregnancy, and molar pregnancy. Pelvic US may also be used in nonpregnancy states to detect tuboovarian abscesses, masses, and hemoperitoneum in the hemodynamically unstable patient.

Image Acquisition

Pelvic US is performed by a transabdominal or endovaginal technique. The transabdominal technique uses a low-frequency transabdominal transducer placed over the lower abdomen in the suprapubic area. Ideally, the transabdominal examination is performed when the patient has a full bladder (an excellent sonographic window), but this may not be necessary if the uterus is large or the patient is thin. Advantages of the transabdominal technique include wider field of view, detection of large pelvic masses, and greater depth of field. In the endovaginal technique, the transducer is placed in the vagina, ideally with a near-empty bladder. Endovaginal transducers are high frequency, providing excellent axial resolution but poor penetration of distant structures. Early intrauterine yolk sacs and fetal poles within gestational sacs may be detected earlier, and ectopic pregnancies can be identified with more accuracy. Transabdominal and, if necessary, endovaginal US in the hemodynamically unstable patient has replaced culdocentesis for detection of ruptured ectopic pregnancy.

Interpretation of the Acquired Images

The diagnosis of intrauterine pregnancy is established when emergency clinicians confidently identify a gestational sac that contains a yolk sac and/or fetal pole and is located within the endometrium (Fig. e5.4). Findings of an ectopic pregnancy include a chorionic ring or gestational sac containing a yolk sac or fetal pole outside the uterus or in an abnormal location in the uterus, such as the cornu or cervix (Fig. e5.5). Although ectopic pregnancy, molar pregnancy, embryonic demise, blighted ovum, subchorionic hemorrhage, and other first-trimester diagnoses are best established by US, image interpretation should remain primarily focused on the search for an intrauterine pregnancy.

Integration of Ultrasound Findings Into Patient Management

Emergency clinician–performed pelvic US has reduced the morbidity of ectopic pregnancy by shortening the time to diagnosis and operating room treatment and has resulted in greater initial...
Image Acquisition

Cardiac US is performed through the transthoracic and transabdominal windows with the use of small curvilinear or phased array transducers. Typical views include the subcostal four-chamber view, parasternal long-axis view, parasternal short-axis view, and apical four-chamber view. Although most emergency clinicians are comfortable with the subcostal view from the FAST examination, the parasternal views are excellent windows for left ventricular assessment. The apical four-chamber view is ideal for comparison of right and left ventricular sizes and function. The subcostal four-chamber view is ideal for assessment of pericardial effusion, whereas the long-axis subcostal view highlights the inferior vena cava and provides an alternative two-chamber view of the left and right ventricles in patients with poor parasternal windows.

Interpretation of the Acquired Images

Pericardial fluid is typically anechoic (Fig. e5.6), although it can contain internal echoes in cases of pericardial hemorrhage or infection. Large pericardial effusions are usually circumferential, although large loculated effusions can have important hemodynamic effects as well. As a result, assessment for pericardial effusion should include interpretation of the subcostal, parasternal, and apical windows, when feasible. Emergency clinicians should be familiar with the location and appearance of an epicardial fat pad to avoid mistaking it for a pericardial effusion.

Although cardiac tamponade is a clinical diagnosis, there are several suggestive echocardiographic features, including diastolic collapse of the right ventricle (Fig. e5.7; Video e5.1), loss of inferior vena cava respiratory variation, and transvalvular flow velocity paradoxus. Assessment for global left ventricular (LV) systolic function can be performed with visual estimation and/or estimation of E-point septal separation (EPSS). EPSS is the distance between the anterior leaflet of the mitral valve and ventricular septum measured using M-mode. A distance greater than 7 mm correlates with poor LV function. Emergency clinicians should recognize that accurate visual estimation of global LV systolic function requires experience and may prefer to categorize systolic function dichotomously as depressed or normal.

Integration of Ultrasound Findings Into Patient Management

Cardiac US performed by emergency clinicians shows good accuracy in the detection of medical and traumatic pericardial effusions and is especially useful for those with comorbid conditions. Identification of pericardial effusion is a common objective of emergency clinicians and is often performed with the FAST examination. Although echocardiography is more sensitive than FAST for pericardial effusion detection, the FAST examination is more commonly performed in the ED.

Cardiac US may be performed with left ventricular function, right ventricular function, and valvular function. The location and appearance of an epicardial fat pad is important in the diagnosis of pericardial effusion. Cardiac US can be used to guide placement of transvenous pacer wires and for pericardiocentesis. Transvenous pacer wires are often placed through central veins, and it can be difficult to place them into the right ventricular apex. US facilitates placement by imaging the wires in real time as they pass through the tricuspid valve and approach the apex of the right ventricle. US can also document ventricular capture.

Cardiac Ultrasound

Identification of Appropriate Patients

Cardiac ultrasound enables rapid assessment for pericardial effusion, global left ventricular systolic function, and right ventricular enlargement and may prove valuable in hemodynamic assessment and early detection of valvular or aortic emergencies. Emergency clinicians should consider cardiac ultrasound in patients with cardiac arrest, suspected pericardial effusion, trauma, chest pain, undifferentiated hypotension, or dyspnea. In a patient who presents with chest pain, US has been studied for the evaluation of pericardial tamponade, pulmonary embolus, cardiogenic shock, aortic dissection, pneumothorax, and bony chest wall fracture. Cardiac US can also be used to guide placement of transvenous pacer wires and for pericardiocentesis. Transvenous pacer wires are often placed through central veins, and it can be difficult to place them into the right ventricular apex. US facilitates placement by imaging the wires in real time as they pass through the tricuspid valve and approach the apex of the right ventricle. US can also document ventricular capture.

Pelvic US in nonpregnancy states has good accuracy for a tubo-ovarian abscess and can lead to faster diagnosis for female patients with abdominal pain. Pelvic US in pregnancy states has good accuracy for the identification of ectopic pregnancies by pelvic US with typical fetal biometry. Heterotopic pregnancies can occur spontaneously at a rate of 1/5000, but occur up to 1 to 3/100 in patients receiving assisted reproductive therapy (ART). As a result, confirmation of an intrauterine pregnancy is accurate by pelvic US with typical fetal biometry. Heterotopic pregnancies can occur spontaneously at a rate of 1/5000, but occur up to 1 to 3/100 in patients receiving assisted reproductive therapy (ART). As a result, confirmation of an intrauterine pregnancy is accurate by pelvic US with typical fetal biometry. Heterotopic pregnancies can occur spontaneously at a rate of 1/5000, but occur up to 1 to 3/100 in patients receiving assisted reproductive therapy (ART). As a result, confirmation of an intrauterine pregnancy is accurate by pelvic US with typical fetal biometry.

Emergency clinicians are adept at the identification of ectopic pregnancies by transabdominal and endovaginal techniques. Pelvic US in nonpregnancy states has good accuracy for a tubo-ovarian abscess and can lead to faster diagnosis for female patients with abdominal pain. Additional online educational content relevant to pelvic ultrasound can be accessed as follows:

- Academic Life in Emergency Medicine—transabdominal, transvaginal reference cards
- Sonoguide website—text, image, video
- AEUS website—narrated lectures, parts I and II
Aortic dissection may be detected by a combination of abdominal and cardiac scanning, with the addition of a suprasternal notch view to the traditional cardiac windows.

Integration of Ultrasound Findings Into Patient Management

Emergency clinicians should visualize the abdominal aorta and measure its diameter from outside edge to outside edge, being careful to include any mural thrombus in the measurement. A diameter greater than 3 cm (Fig. e5.8) constitutes an abdominal aortic aneurysm, but risk of rupture increases with size and is rare with aneurysms smaller than 4.5 cm.

A linear echogenic flap, anywhere across the lumen of the aorta, is suggestive of aortic dissection (Fig. e5.9), and may be associated with a different Doppler flow pattern on either side of the flap. The cardiac US examination may demonstrate an unexplained pericardial effusion, a dilated aortic root (>4 cm); aortic insufficiency, and/or a linear echogenic flap in the ascending aorta, aortic arch (through the suprasternal notch view), descending thoracic, or abdominal aorta.

Integration of Ultrasound Findings Into Patient Management

Emergency clinician use of US for AAA detection has shown good accuracy compared with other imaging modalities. It also has the advantage of quickly detecting pericardial effusion, assessment of LV function, and evaluation of patients with undifferentiated shock. US has a role in cardiac arrest, where it can detect ventricular motion in asystole and pulseless electrical activity, confirm cardiac standstill and its associated poor prognosis, and detect ventricular capture when the patient is transcutaneously or transvenously paced. There is a developing role for bedside transesophageal echocardiography in the evaluation of the periarrest patient; advanced cardiac life support guidelines have suggested minimizing noncardiopulmonary resuscitation intervals.

Several US protocols have been developed to evaluate undifferentiated hypotension. Cardiac US windows with the addition of abdominal views can assess for effusion, global ventricular activity, ventricular chamber size, inferior vena cava size, respiratory changes, peritoneal fluid, and abdominal aortic aneurysm (AAA) to narrow the differential diagnosis.

Additional online educational content relevant to cardiac ultrasound can be accessed as follows:

Abdominal Vascular Ultrasound

Identification of Appropriate Patients

Emergency clinicians use abdominal US to detect an AAA in patients with flank, abdominal, or back pain, and to evaluate unexplained hypotension in the older patient. The use of US to detect aortic dissection has also been described.

Image Acquisition

The examination is performed with a curvilinear array or phased array low-frequency transducer, and requires significant pressure to displace the overlying bowel gas, which can obscure the abdominal aorta. The technique involves imaging from the subxiphoid space to the umbilicus and visualizing the aorta from the diaphragm to its bifurcation in transverse and longitudinal planes. If an aneurysm is identified, a view of Morison’s pouch and/or the splenorenal space may be obtained to assess for intraperitoneal or retroperitoneal fluid. Proximal iliac arteries may also be evaluated if technically feasible and indicated by clinical suspicion.
management implications in older patients with lower back pain, for whom the elimination of the presence of an AAA is important for medical decision making. Screening for AAA in the ED with US has been shown to be effective.

Although intraperitoneal and/or retroperitoneal hemorrhage may be detected, abdominal ultrasound is insufficiently sensitive to exclude a leaking AAA, and CT should be performed in patients with aneurysms in whom the clinical picture suggests the possibility of rupture. Likewise, emergency US may demonstrate evidence of an aortic dissection but should not be used to exclude this potentially life-threatening diagnosis.

Additional online educational content relevant to aorta ultrasound can be accessed as follows:

- Emergency Ultrasononography website—video gallery

**Biliary Ultrasound**

**Identification of Appropriate Patients**

Biliary US to detect gallstones and associated cholecystitis was one of the early applications of US in emergency medicine and should be considered in patients with right upper quadrant pain, epigastic pain, jaundice, and sepsis without a clear source.

**Image Acquisition**

The examination is performed with a low-frequency curved linear array or phased array transducer. Subcostal, intercostal, and flank windows will facilitate visualization of the gallbladder, which should be evaluated in two orthogonal (perpendicular) planes. A complete evaluation includes visualization and measurement of the common bile duct, typically located just cephalad to the gallbladder neck.

**Interpretation of the Acquired Images**

The diagnosis of cholelithiasis is made by identification of echogenic foci within the gallbladder lumen, with associated shadowing. Other image patterns include stones with indistinct shadow, sludge, and the wall-echo-shadow (WES) sign seen in a gallbladder full of gallstones. Signs of cholecystitis include a dilated gallbladder, increased gallbladder wall thickness (>3 mm), sonographic Murphy’s sign, and pericholecystic fluid (Fig. e5.10). A nonmobile stone in the gallbladder neck is highly suggestive of eventual cholecystitis. A common bile duct larger than 6 mm in people younger than 60 years and larger than 10 mm in older patients may indicate choledocholithiasis.

**Integration of Ultrasound Findings Into Patient Management**

Biliary US is fast and accurate, with a reported sensitivity of 87% to 94% and specificity of 82% to 96% in the detection of gallstones, comparable to radiologic ultrasound.18,19 Emergency clinicians should be aware that small stones may be difficult to visualize with the resolution available from a portable ultrasound system and that comprehensive radiologic ultrasound may be indicated in cases of high clinical suspicion and/or obese patients with challenging sonographic windows.

Additional online educational content relevant to biliary ultrasound can be accessed as follows:
- Academic Life in Emergency Medicine—reference card
- Sonoguide website—text, image, video
- AEUS website—narrated lecture
- Emergency Ultrasonography website—video gallery

**Urinary Tract Ultrasound**

**Identification of Appropriate Patients**

Renal and urinary tract US can detect hydronephrosis and/or urinary retention. The lack of ionizing radiation and rapidity of renal US make it an attractive option for the investigation of patients with unexplained flank, back, or groin pain.20 In addition, bladder US is useful for the detection of a full bladder, presence and location of a Foley catheter, and guidance during suprapubic aspiration or Foley placement.

**Image Acquisition**

Renal US includes orthogonal views of the kidneys, with an emphasis on visualization of the renal pelvis. In addition, visualization of the bladder can diagnose secondary hydronephrosis from an obstructed bladder stone and may demonstrate nonobstructive ureteral jets through the use of Doppler US. The sonographic windows for the two kidneys are similar to those used in the trauma upper quadrant views, with the exception that the patient may be rolled toward the opposite side so that the transducer may be placed more posteriorly on the back, if necessary. The bladder view is performed from the suprapubic window, and calculations of volume may be made with on-machine calculators or by using the formula:

\[
\text{Length} \times \text{width} \times \text{height} \times 0.52 = \text{volume}
\]

**Interpretation of the Acquired Images**

Hydronephrosis is characterized by dilation and anechoic fluid accumulation within the renal pelvis and calyces (Fig. e5.11) and can range from mild to severe. Renal and/or ureteral calculi may be identified as echogenic foci with associated shadowing and are usually located within the kidney (nonobstructive) or in the renal pelvis, proximal ureter, or ureterovesicular junction. The use of color Doppler may help identify urolithiasis by visualization of twinkling artifact.

**Integration of Ultrasound Findings Into Patient Management**

A recent multicenter randomized controlled trial comparing CT to emergency US and radiologic US as the initial imaging modal-
sound in combination with a D-dimer test, which, if abnormal, required a 1-week follow-up visit. Both strategies were equally efficacious in the detection of symptomatic DVT and overall outcomes at 3-month follow-up. Most studies evaluating two-zone compression ultrasonography have been performed in an ambulatory outpatient population; therefore, bedridden, postoperative, or otherwise immobile patients may require more comprehensive imaging protocols to exclude DVT. Depending on the skill of the sonographer, patient characteristics, and availability of follow-up, ED US may guide lower extremity DVT institutional protocols.

Additional online educational content relevant to DVT ultrasound can be accessed as follows:
- Practical Ultrasound Series—deep venous thrombosis iBook
- Academic Life in Emergency Medicine—reference card
- Sonoguide website—text, image, video
- AEUS website—narrated lecture
- Emergency Ultrasonography website—video gallery

Deep Venous Thrombosis Ultrasound

Identification of Appropriate Patients

Emergency clinicians should consider using emergency US to assess for DVT in patients with swollen or painful extremities. In some cases, evaluation for DVT may be indicated in patients with suspected pulmonary embolism because the presence of a DVT may facilitate initiation of anticoagulation prior to, or in lieu of, other imaging modalities.

Image Acquisition

Lower extremity venous compression ultrasound is typically performed with a high-frequency linear array transducer. The two-zone technique involves evaluating and compressing the common femoral vein from the saphenofemoral junction through the bifurcation of the femoral vein and the popliteal vein through its trifurcation. The three-zone technique adds the femoral vein from its origin through the distal thigh. Evaluation of upper extremity veins is less commonly performed by emergency clinicians; Doppler US is required for the subclavian vein, which is not compressible under the clavicle.

Interpretation of the Acquired Images

The lack of compressibility is the hallmark of deep venous thrombosis, although newer generation ultrasound systems commonly have sufficient resolution to allow direct visualization of echogenic thrombi as well (Fig. e5.12).

Integration of Ultrasound Findings Into Patient Management

The accuracy of this technique ranges from 87% to 99%, depending on operator experience. Hospital charges and time in the ED are reduced for patients who have bedside venous US performed to rule out DVT. A large randomized trial has compared radiology performed via whole-leg ultrasound versus a two-point ultrasound in combination with a D-dimer test, which, if abnormal, required a 1-week follow-up visit. Both strategies were equally efficacious in the detection of symptomatic DVT and overall outcomes at 3-month follow-up. Most studies evaluating two-zone compression ultrasonography have been performed in an ambulatory outpatient population; therefore, bedridden, postoperative, or otherwise immobile patients may require more comprehensive imaging protocols to exclude DVT. Depending on the skill of the sonographer, patient characteristics, and availability of follow-up, ED US may guide lower extremity DVT institutional protocols.

- Emergency Ultrasonography website—video gallery

Thoracic Ultrasound

Identification of Appropriate Patients

Thoracic ultrasound should be considered in patients with chest pain and/or dyspnea in whom the emergency clinician suspects pleural effusion, pneumothorax, pneumonia, or pulmonary edema.

Image Acquisition

Thoracic ultrasound is often performed with a low-frequency curvilinear array or phased array transducer, although visualization of lung sliding may be enhanced, if necessary, by the use of a high-frequency linear array transducer. The anterior, anterolateral, and posterolateral areas of the thorax are investigated, with an emphasis on visualization of lung sliding, A-lines, B-lines, consolidation, and effusion.

Interpretation of the Acquired Images

Lung sliding, a normal finding, is identified as the visceral and parietal pleura glide against each other during normal respiration (Video e5.2). A-lines, equally spaced horizontal echogenic artifacts deep to the pleural line, are also a normal finding.
The visualization of lung sliding excludes the presence of a pneumothorax at that location on the patient's chest wall. Although M-Mode and color Doppler techniques have been described as adjuncts to the evaluation of patients with suspected pneumothorax, neither is a necessary component of the examination. Absent lung sliding (Video e5.3) can result from a variety of causes in addition to pneumothorax, including pleural adhesions, pleurodesis, partial or complete pneumonectomy, and contralateral mainstem bronchus intubation. A lung point sign is identified at the border of the pneumothorax, where the image shows absent lung sliding until the lung moves into the interspace with respiration (Fig. e5.15).

Pulmonary edema is indicated by the presence of B-lines, which are hyperechoic reverberation artifacts that arise from the pleura, move with respiration, extend off the screen without fading, and erase the normal A-line pattern (Fig. e5.14). Normally found in small numbers in the dependent areas of the lung, the widespread distribution of these artifacts indicates increased interstitial and/or alveolar thickening due to fluid accumulation (edema) or scarring (fibrosis).

Lobar pneumonia is visualized as echogenic so-called liver-like echogenicity as the lung accumulates fluid with consolidation. The dynamic air bronchogram, hyperechoic areas within bronchi that move with respiration, usually within consolidated lung, has been described as another sign of alveolar consolidation.

Pleural fluid appears as an anechoic collection above the diaphragm (Fig. e5.15), although internal echoes may be present in cases of chronic, infected, or loculated effusions.

Integration of Ultrasound Findings Into Patient Management

The accuracy of US for the detection of pneumothorax (sensitivity, 100%; specificity, 98%) is better than that of plain chest radiography in the acute setting, with performance characteristics approaching that of thoracic CT scanning.24 US evaluation of the acutely dyspneic patient has been associated with increased diagnostic accuracy as compared to traditional clinical, laboratory, and imaging protocols,25,26 particularly for the identification of patients with a cardiogenic cause of acute dyspnea.

Additional online educational content relevant to thoracic ultrasound can be accessed as follows:

- Academic Life in Emergency Medicine—reference card
- AEUS website—narrated lecture
- Ultrasound podcast—narrated lectures, parts I and II
- Emergency Ultrasonography website—video gallery

Ocular Ultrasound

Identification of Appropriate Patients

Ocular US is a useful modality for intraocular diseases such as retinal detachment, retinal hemorrhage, vitreal hemorrhage, intraocular foreign body, dislocated lens, and retro-orbital hemorrhage. In addition, the globe, pupillary size, and extraocular movements can be examined, even in the presence of facial swelling.

Image Acquisition

The structures of the eye provide an excellent acoustic window, and short-duration, B-mode US over a closed eyelid allows the anterior and the posterior chambers to be well visualized. An ocular preset should be selected to minimize the thermal exposure to the retina during the examination. The vitreous chamber is evaluated by scanning through the globe in orthogonal planes in low-gain and high-gain settings.
Public Health and Humanitarian Emergencies

Interpretation of the Acquired Images

A linear echogenic structure in the vitreous chamber seen with low-gain imaging is suggestive of a retinal detachment (Fig. e5.16), whereas a thinner linear structure seen only with high-gain imaging is more consistent with a vitreous detachment. The diagnosis of vitreous hemorrhage, retinal detachment, and lens dislocation may all be facilitated through the use of kinetic echography, where the patient shifts the gaze in different directions during the examination.

Integration of Ultrasound Findings Into Patient Management

The reported sensitivity of ocular US for retinal detachment by emergency clinicians is 100%, and the specificity is 83% to 92%. Additional online educational content relevant to ocular ultrasound can be accessed as follows:

- Academic Life in Emergency Medicine—reference card
- Sonoguide website—text, image, video
- AEUS website—narrated lecture

Soft Tissue Ultrasound

Identification of Appropriate Patients

Soft tissue US is used to differentiate cellulitis from abscess, detect foreign bodies and hernias, and evaluate other soft tissue pathologic processes, including masses, pseudoaneurysms, and glands. US can also differentiate peritonsillar abscess from cellulitis and can be used to guide peritonsillar aspiration.

Image Acquisition

A high-frequency linear transducer is used to visualize the entire affected area in two orthogonal planes. Evaluation for peritonsillar abscess is best performed with the endocavitary transducer.

Interpretation of the Acquired Images

Cellulitis or edema results in an echogenic pattern, with cobblestoning between fat lobules (Fig. e5.17). Abscesses are irregular hypoechoic to anechoic collections, typically located within the subcutaneous layer (Fig. e5.18), but may also connect with the skin surface. US is diagnostic in soft tissue disease for cellulitis, abscess and, in some case series, necrotizing fasciitis.

The detection of foreign bodies is characterized by variable echogenicity in the tissue, with shadowing beneath the foreign body. Metal foreign bodies, such as bullets and intrauterine devices, have characteristically high-reflective echogenicity and ring-down artifacts. Use of a water bath may aid in the detection of superficial foreign bodies.

Integration of Ultrasound Findings Into Patient Management

Ultrasound has greater sensitivity and specificity than a clinical examination for the detection of soft tissue abscess. In other studies, the use of US changed management for 50% of adult patients and 22% of children with clinical cellulitis. One study has shown that incision and drainage are superior to US-guided aspiration in a cohort of patients with soft tissue infection with respect to resolution at 1 week (80% vs. 26%, respectively).

Additional online educational content relevant to soft tissue ultrasound can be accessed as follows:

- Academic Life in Emergency Medicine—reference card
- Sonoguide website—text, image, video
- Emergency Ultrasonography website—video gallery

Musculoskeletal Ultrasound

Identification of Appropriate Patients

Patients with suspected joint effusion or muscular, tendinous, or ligamentous injury may benefit from US-guided evaluation.
Emergency US is excellent for the detection of fluid in joints, confirmation of effusions, and guidance of drainage procedures. In addition, the diagnosis of ligamentous injuries and muscle avulsion and hemorrhage has also been reported.

**Image Acquisition**

Musculoskeletal US is typically performed with a high-frequency linear array transducer with imaging of the affected joint, muscle, tendon, ligament, or bone in two orthogonal planes. As with the physical examination, US detection of tendon and muscle injury is often assisted by movement of the limb. Comparison with the contralateral side may also be helpful. Water bath techniques provide a better acoustic window for shallow tissue, such as fingers.

**Interpretation of the Acquired Images**

Joint effusions can be anechoic or echogenic, depending on type and age. Muscle and tendon abnormalities are detected by anechoic and heterogeneous abnormalities. Tendons and their anisotropic longitudinal fibrils can be visualized near joints, with pathologic tears appearing as a discontinuity of the tendon (Fig. e5.19). Muscles are hypoechoic and appear striated, with echogenic borders. Tears and hemorrhage are interruptions of this normal pattern.

The characteristic echogenic appearance of bony cortex with associated shadowing is used to identify normal bone and its contour. Fractures are seen as a defect in the bony cortex (Fig. e5.20).

**Integration of Ultrasound Findings Into Patient Management**

Ultrasound identification of tendon disruption is highly accurate in the knee extensors and Achilles tendon. Evaluation of the rotator cuff requires considerable experience but offers accuracy that rivals that of magnetic resonance imaging.

Additional online educational content relevant to Musculoskeletal Ultrasound can be accessed as follows:

- Sonoguide website—text, image, video
- AEUS website—narrated lecture
Integration of Ultrasound Findings Into Patient Management

In small studies, experienced emergency clinicians have accurately diagnosed testicular pain with high sensitivity and specificity. Additional online educational content relevant to testicular ultrasound can be accessed as follows:

- Academic Life in Emergency Medicine—reference card
- Sonoguide website—text, image, video

Bowel Ultrasound

The use of bedside US for the evaluation of appendicitis, small bowel obstruction and other bowel disease has been an area of increasing interest. There has been variable experience with the use of graded compression US to detect appendicitis (Figs. e5.22 and e5.23) and, although there has been considerable interest in an ultrasound-first approach to suspected appendicitis, the accuracy of emergency clinician–performed US for appendicitis has been equivocal. The use of US for diverticulitis, intussusception, volvulus, and small bowel obstruction has also been reported. Hernias may also be detected as masses in the ventral, inguinal, paramedian, femoral, and scrotal areas.

Additional online educational content relevant to bowel ultrasound can be accessed as follows:

- AEUS website—narrated lectures, parts I and II

Pediatric Emergency Ultrasound

The use of US for children in the ED has two paths, one that mirrors the applications that have been used for adults and another that explores the more specific pediatric abdominal applications.

The FAST examination for evaluation of abdominal trauma in children is specific (98%), but the sensitivity is only 20%, making it difficult to use without further imaging or other testing. In addition, specific pediatric abdominal applications that are common in the radiology suite have been gaining in popularity, as evidenced by studies evaluating the role of emergency US in patients with suspected intussusception, appendicitis, and pyloric stenosis.

Ultrasound for Procedural Guidance

In 2001, in response to the Institute of Medicine report To Err Is Human, the Agency for Healthcare Research and Quality (AHRQ) sanctioned a report on actions that may improve patient safety. The report contained a recommendation for US guidance for internal jugular central line insertion that was reiterated in the revised 2013 report. Since the original report, the use of US for procedural guidance has expanded for many emergency procedures (Table e5.1), and is advocated for error reduction.

Procedural guidance can be static or dynamic. Static guidance suggests that US has been placed over the anatomic area, and the area has been marked after noting angle and distance information. Dynamic guidance describes procedures performed with real-time US visualization of the needle entering the anatomic area.

Additional online educational content relevant to procedural ultrasound can be accessed as follows:

- Sonoguide website—text, image, video
- AEUS website—narrated lectures, parts I and II

Vascular Access Procedures

There are two common approaches to vein cannulation—out of plane, in which the vein is imaged in short axis and appears as a circular structure on the screen, and in plane, in which the vein is imaged in long-axis and appears as a tubular structure traversing the width of the screen. In the out-of-plane approach, the needle bisects the transducer at its midpoint (Fig. e5.24). In the in-plane approach, the needle is introduced under the long axis of the transducer (Fig. e5.25). Although the out-of-plane approach is more popular with novices, the in-plane approach may be safer in experienced hands due to the continuous visualization of the needle tip during the entire procedure. In addition, an oblique axis in-plane technique has been described, where the vessels are imaged at an oblique angle while the needle is inserted in plane. Although there have been no large-scale trials evaluating this technique, it may offer the benefit of continuous needle visualization while offering improved visibility of surrounding structures not possible with use of the long-axis, in-plane technique.

The most studied and advocated use of US procedural guidance is for central venous catheter insertion. Both the AHRQ and National Institute for Health and Clinical Excellence have recommended US guidance for central line insertion. US guidance for
internal jugular central line insertion can be recommended as a safe and best practice.\textsuperscript{32} (Fig. e5.26).

Ultrasound guidance enables the emergency clinician to assess the internal jugular for overlap with the carotid artery, vessel diameter, and presence of luminal clot or vessel obliteration (Videos e5.4 and e5.5). Internal jugular central line insertion has been studied in the ED, intensive care unit, and radiology suite. In the ED, US-guided internal jugular cannulation is associated with decreased time to vessel penetration and improved success in the difficult to stick patient, improved overall and first-attempt success rates, reduced time to insertion, and reduced complication rate. The Valsalva maneuver and Trendelenburg position may assist in increasing the cross-sectional area of the internal jugular vein.

US does not prevent posterior vein wall penetration, as reported in case reports and simulated models.\textsuperscript{33} Adverse events (eg, hematoma, arterial cannulation, pneumothorax, unsuccessful placement) can occur in up to 20% of patients undergoing US-guided internal jugular catheterization.\textsuperscript{34} US improves procedural success in subclavian vein cannulation, whether cannulated via the infraclavicular or supraclavicular subclavian approach.\textsuperscript{35,36}

Emergency clinicians can also insert peripheral intravenous (IV) catheters successfully in patients with difficult access using

emergency US, with one study demonstrating a marked reduction in the need for central venous catheter placement in ED patients with poor IV access. Only one randomized study has shown no differences in number of attempts, time to successful catheterization, or patient satisfaction. Veins that are large in width or at moderate depth (<1.6 cm) have a higher success rate. Nurses and ED technicians have also been taught to use US for peripheral venous guidance.

Arterial access, including radial artery aspiration and cannulation, is more successful with US guidance. Sonographic confirmation of intraosseous needle placement has also been described based on the detection of extraosseous or intraosseous Doppler flow.

**Torso Drainage Procedures**

US can facilitate procedures such as paracentesis, thoracentesis, and pericardiocentesis by confirming the presence and amount of fluid as well as its relative location to key anatomic structures. Paracentesis, including US-guided diagnostic peritoneal lavage, can be performed with static or dynamic ultrasound guidance. US is useful for identifying the deepest location of ascites and presence of obstructing bowel loops or superficial vascular structures. Thoracentesis is assisted by considering the diaphragm as the most inferior anatomic landmark to avoid solid organ injury. The routine use of sonography has been associated with a reduced rate of pneumothorax and tube thoracostomy. Pericardiocentesis also can be facilitated by location of the best window—subcostal, apical, or parasternal long—and needle guidance into the pericardial space, lessening the likelihood of cardiac puncture.

**Soft Tissue and Musculoskeletal Procedures**

Foreign bodies can be identified and removed with the guidance of US. Static guidance marks the location, depth, and size of the foreign body. Dynamic guidance requires an incision remote from the overlying skin to allow the probe to monitor the procedure. Arthrocentesis may be assisted by US to detect effusion, identify joint landmarks, and confirm the needle tip in the joint. Use of US reduces the number of attempts and increases the overall success rate for most joint aspirations, but has not shown benefit in knee joint aspiration. Arthrocentesis of the adult and pediatric hip, in addition to other joints, has been reported, with good success.

US may assist hematoma aspiration and blocks by directing the needle into the affected site. It can be used as an alternative to fluoroscopy for the guidance of fracture reduction because assessment of alignment can be performed before and after reduction (Fig. e5.27).

**Nerve Blocks**

US-guided nerve blocks confirm needle placement adjacent to the target nerve and allow anesthetic to be delivered safely and effectively around the nerve (Fig. e5.28). Multiple US-guided nerve blocks have been described in the emergency medicine and anesthesia literature, and it is clear that most peripheral nerve blocks benefit from the assistance of US. US-guided femoral or fasciiliaca blocks have an opioid-sparing effect in older patients with femur fractures and have been increasingly incorporated into standardized care protocols for geriatric orthopedic trauma.

**Lumbar Puncture**

Ultrasound can be used to facilitate lumbar puncture by identification of the spinous processes in patients without palpable anatomic landmarks. This procedure is most often performed using a static technique, where an appropriate needle insertion site is identified and marked prior to sterile skin preparation, and the procedure is then performed without dynamic US guidance.
Out-of-Hospital Ultrasound: Disasters and Remote Settings

The use of ultrasound has been described in European and other settings by emergency clinicians and paramedics in the out-of-hospital arena, including ground, helicopter, air, and space, for FAST and abdominal aorta examinations. The military has used US extensively in combat situations, including the frontline, combat support hospital, and tertiary hospital settings. US was used to facilitate the care of patients injured in the Haitian earthquake in 2010, Boston marathon bombing in 2013, and a number of other casualty situations.40,41

US interpretation may be enhanced by satellite and telesonography systems that allow remote guidance and interpretation. In emergency medicine practice, the performance and interpretation of ultrasonography for trauma (FAST), focused cardiac ultrasound, abdominal aortic aneurysm assessment, and procedural guidance for central venous catheter placement. The “four Is” of ultrasound are as follows: (1) identification of appropriate patients for whom emergency ultrasound is likely to be valuable; (2) image acquisition; (3) interpretation of the acquired images; and (4) integration of the ultrasound findings into patient management.

**KEY CONCEPTS**

- Emergency ultrasound is performed and interpreted by the emergency clinician at the bedside.
- Emergency ultrasound is designed to answer focused clinical questions.
- The key to proficiency in emergency ultrasound is practice.
- Credentialing guidelines exist to guide emergency clinicians in the acquisition of this important skill.
- All emergency clinicians should be familiar with the resuscitative applications of emergency ultrasound, including focused assessment with sonography for trauma (FAST), focused cardiac ultrasound, abdominal aortic aneurysm assessment, and procedural guidance for central venous catheter placement.

**REFERENCES**

**CHAPTER e5: QUESTIONS & ANSWERS**

**e5.1.** Emergency ultrasound (US) is defined by the physical location of the emergency patient.
A. True
B. False

**Answer:** B. Emergency US is not defined by location but by patient need. Patients may be in remote locations, prehospital, in the emergency department (ED), in the intensive care unit (ICU), or elsewhere in the hospital.

**e5.2.** Which are not typically involved with emergency US examinations?
A. Acute symptom
B. Comprehensive mapping of an organ
C. Emergency sign
D. Focused area of the body
E. Physiologic pattern

**Answer:** B. Comprehensive mapping of organs is not typical of emergency US examination. The other items are characteristics of US done for emergency and symptom-based examinations.

**e5.3.** Which frequency range defines US?
A. Less than 0.2 Hz
B. Over 2 Hz
C. Over 200 Hz
D. Over 20,000 Hz
E. Over 2 million Hz

**Answer:** D. US is defined as sound with frequency over 20,000 Hz.

**e5.4.** Which of the following performance characteristics is true for higher frequency probes?
A. Deeper penetration, higher resolution
B. Deeper penetration, poorer resolution
C. Superficial penetration, higher resolution
D. Superficial penetration, poorer resolution

**Answer:** C. Higher frequency probes penetrate in superficial areas but generally give good resolution.

**e5.5.** Which type of US has the best resolution when the probe is perpendicular to the object of interest?
A. Doppler US
B. Gray scale US

**Answer:** B.

**e5.6.** Which of the following is not considered safe practice for performing emergency US?
A. Cleaning surface probes with spray or wipe
B. Imaging over a body part continuously for 60 minutes
C. Special endovaginal cleaning
D. Use of the ALARA (as low as reasonably achievable) principle
E. Transducer covers during sterile procedures

**Answer:** B. There are thermal effects to US over a long duration.

**e5.7.** Which of the following areas is not scanned during an EFAST examination?
A. Orbital space
B. Pericardial space
C. Peritoneal space
D. Pleural space

**Answer:** A. Orbital space is not typically part of the EFAST.

**e5.8.** Sensitivity is typically greater than specificity for FAST examination.
A. True
B. False

**Answer:** A. The FAST examination is typically more specific than sensitive.

**e5.9.** Which of the following is the most appropriate use for emergency pelvic US in early pregnancy?
A. To rule out adnexal masses
B. To rule out ectopic pregnancy
C. To rule out fibroids
D. To rule in intrauterine pregnancy

**Answer:** B. The most appropriate use of US is to rule in intrauterine pregnancy, which greatly decreases the chances for an ectopic pregnancy. Evaluation of the adnexa and detection of an ectopic pregnancy requires a higher level of equipment and training than reliably available in an emergency situation.

**e5.10.** Which of the following is an advantage of endovaginal US over using a transabdominal window?
A. Better ability to assess Morison’s pouch
B. Deeper penetration of ultrasound
C. Greater field of view
D. Higher resolution for assessment of gestational structures

**Answer:** D. An endovaginal transducer allows imaging closer to the structures of interest and eliminates poor acoustic imaging due to body habitus or artifacts such as bowel gas.
e5.11. Which of the following is not a typical use of cardiac US by emergency clinicians?
A. Focal wall motion abnormalities
B. Global left ventricular function
C. Pericardial effusion
D. Pseudo-PEA (pulseless electrical activity)
E. Right ventricular dilatation

Answer: A. Focal wall motion abnormalities are more difficult to detect than the other conditions.

e5.12. Which of the following has been demonstrated with the use of cardiac US?
A. Reduced time to central line in sepsis
B. Reduced time to computed tomography (CT) in blunt obstetric trauma
C. Reduced time to operating room (OR) for penetrating cardiac trauma
D. Reduced time to pelvic fixator in blunt pelvic trauma

Answer: C. Emergency cardiac US has been shown to reduce time to the OR for penetrating cardiac trauma and has greatly decreased the need for emergency thoracotomy in critical patients.

e5.13. Which of the following is not an indication for emergency US of the abdominal aorta?
A. Detecting aortic dissection
B. Detecting aortic occlusion
C. Placing aortic stents
D. Ruling out abdominal aortic aneurysm (AAA)

Answer: D. Ultrasound of the aorta is sensitive to detect AAAs and can rule out the condition with high accuracy. It is also useful to detect dissection and occlusion, but emergency clinicians do not place aortic stents.

e5.14. Which of the following is a typical use for biliary US by emergency clinicians?
A. Biliary stricture
B. Gallstones
C. Hepatic cyst detection
D. Hepatic hemangioma

Answer: B. Gallstones are a common finding that can direct emergency management and disposition. The other conditions are not easily detected and do not need to be diagnosed on an emergency basis.

e5.15. Which of the following is not a characteristic of sonographic cholecystitis?
A. Gallbladder septation
B. Gallbladder wall thickening
C. Gallstones
D. Pericholecystic fluid

Answer: A. All the findings provide evidence for cholecystitis except septation of the gallbladder.

e5.16. Dilation of which genitourinary (GU) structure(s) is typically seen with US?
A. Bladder
B. Midureter
C. Renal calyces
D. Renal pelvis

Answer: B. Midureter

e5.17. A typical emergency lower extremity deep venous thrombosis (DVT) protocol includes compression of which of the following veins?
A. Common femoral
B. Deep peroneal
C. Posterior tibial
D. Transcapular

Answer: A. Compression of the common femoral vein assists in the diagnosis of DVT.

e5.18. Which of the following is the correct order of imaging for the sensitivity of detecting a pneumothorax?
A. Chest x-ray (CXR) > CT > US
B. CT > CXR > US
C. CT > US > CXR
D. US > CT > CXR

Answer: C. CT > US > CXR is the correct order.

e5.19. Which of the following is not a common abnormal pattern detected by lung US?
A. Anechoic collection in the dependent pleural space
B. B-lines in the bases of the lung
C. Increased B-lines in the apices of the lung
D. Lack of sliding after penetrating chest trauma
E. Liver-like lesions with air bronchograms

Answer: B. B-lines in the bases of the lung are not common.

e5.20. Which of the following can be diagnosed by ocular ultrasound?
A. Glaucoma
B. Pterygium
C. Retinal detachment
D. Uveitis

Answer: C. Retinal detachment can be seen on ocular ultrasound. US is not useful for the detection of the other conditions listed.

e5.21. Which of the following is not true of soft tissue US in the ED?
A. US aspiration is superior to incision and drainage (I&D) in regard to resolution at 1 week.
B. US changes management of clinical cellulitis in 50% of adult patients.
C. US is more sensitive and specific than clinical examination.
D. Water baths may assist in the detection of superficial foreign bodies.

Answer: A. I&D is superior to US-guided aspiration in regard to abscess resolution at 1 week. The other statements are true.

e5.22. Which of the following has not been diagnosed by musculoskeletal US in the ED?
A. Cervical disk impingement
B. Fracture of long bones
C. Hematomas
D. Joint effusions
E. Tendon lacerations

Answer: A. Musculoskeletal US has been used for all the listed conditions except cervical disk impingement.
e5.23. Dynamic US guidance reflects sonographic real
visualization of the needle tip into the particular
anatomic region.
   A. True
   B. False

Answer: A. True

e5.24. During a US-guided procedure, which of the following is
not a benefit of the long-axis approach to US guidance?
   A. Depth information
   B. Medial-lateral information
   C. Visualization of the needle shaft tip
   D. Visualization of the needle tip

Answer: B. Medial-lateral information is lacking because the
plane of the US is aligned with the needle.

e5.25. Which of the following procedures is benefited by US
guidance?
   A. All of these
   B. Arthrocentesis
   C. Internal jugular guidance
   D. Pericardiocentesis
   E. US-guided nerve blocks

Answer: A. All the listed procedures benefit from US guidance.

Video e5.1. Pericardial effusion with tamponade. This subcostal cardiac
view demonstrates a large circumferential pericardial effusion, with dia-
stolic collapse of the right ventricle.

Video e5.2. Normal lung sliding. The hyperechoic pleural line is sliding
normally in an interspace between two ribs.

Video e5.3. Absent lung sliding. The pleural line is visualized between
two ribs but does not demonstrate normal sliding movement.

Video e5.4. Internal jugular vein, located anterior to the carotid artery,
with normal compressibility.

Video e5.5. Internal jugular vein cannulation. During dynamic ultra-
sound-guided central line placement, the hyperechoic needle with a
ring-down artifact is visualized in the internal jugular vein. Care must be
taken to visualize the needle tip at all times to avoid posterior wall or
carotid puncture.

PRINCIPLES OF OBSERVATION MEDICINE

THE OBSERVATION APPROACH

CLINICAL CONDITIONS

Evaluation of Critical Diagnostic Syndromes

Treatment of Emergency Conditions

SUMMARY

*For the complete chapter text, go to the Expert Consult website. To access your account, look for your activation instructions on the inside front cover of this book.

KEY CONCEPTS

- Hospitalization can often be avoided by providing short-term care (<24 hours) in observation units for certain medical disorders, such as chest pain, deep vein thrombosis (DVT), upper gastrointestinal (GI) bleeding, syncope, transient ischemic attack (TIA), trauma, asthma, atrial fibrillation, congestive heart failure (CHF), dehydration, pneumonia, and pyelonephritis.
- The use of observation units results in cost savings and improved patient satisfaction with care.
- Observation care is on an outpatient basis and is not necessarily delivered in a specific location.
- Observation is used to provide additional time for therapeutics and/or diagnostics for patients with an uncertain need for inpatient admission.
- Observation care is often influenced by payer policies and is congruent with recent national efforts to increase patient safety while also reducing unnecessary costs.
- Evidence-based observation care is delivered in a dedicated area for this purpose, using condition- or complaint-specific protocols of care.
- When used appropriately and at benchmark levels of quality and efficiency, observation visits can reduce the duration and thus the cost of hospital care for eligible patients while also reducing the incidence of unsafe discharges to home.
- The role of observation care is best studied in chest pain patients but, over the past several decades, patients with many other conditions have shown to be managed effectively using observation.
- Emergency clinicians should play a central role in identifying and managing observation patients.
Observation Medicine and Clinical Decision Units

**CHAPTER e6**

Christopher W. Baugh | Louis Graff IV

---

**PRINCIPLES OF OBSERVATION MEDICINE**

Observation services are an extension of emergency department (ED) services specifically designed to address unmet patient needs. They improve patient care by extending the evaluation and management of selected patients who require further hospital care following an ED visit, but do not clearly need an inpatient admission. Observation is an outpatient service, can be delivered by any specialty, and is not tied to a specific site of care. However, protocol-driven observation care in a dedicated unit results in lower length of stay and cost, equivalent clinical outcomes, and even higher patient satisfaction versus routine inpatient management. The benchmark rate of discharge to home from an observation unit is about 80%, with an average length of stay close to 15 hours. The cost to evaluate and treat these patients is nearly half that incurred by routine inpatient admission, a savings of $1572, on average. In addition, the threshold for extended evaluation (traditionally provided only with inpatient hospitalization) is lowered—emergency clinicians are no longer forced into a dichotomy of home versus admission. Patients with atypical signs and symptoms are more fully evaluated to rule out serious conditions, such as acute myocardial infarction or acute appendicitis. Thus, in addition to lower costs, there is also a simultaneous decrease in the inadvertent release home of patients with serious disease.

An ED observation unit is an area dedicated to provide these short-term services, typically for up to 24 hours but, in rare cases, care may extend beyond this time frame. In 2013, the Centers for Medicare & Medicaid Services introduced the 2 Midnight Rule, wherein patients with an expected hospital stay of less than two midnights should be designated observation patients. Although this type of influential payer policy makes strict limits on observation length of stay less feasible, providers need to be wary of the threat of mission creep, resulting in prolonged stays that are out of scope for care by emergency emergency clinicians. Names given to observation units vary; they include chest pain unit, clinical decision unit, and rapid diagnostic treatment unit. An ED-based observation unit is not a holding unit. A holding unit stems from hospital overcrowding and is an area where patients admitted to the hospital are held passively until they can be transferred to an inpatient bed.

Two categories of patients benefit from extension of the usual 2- or 3-hour ED visit to up to 24 hours. One group is selected ED patients with a critical diagnostic syndrome (Box e6.1). These are patients whose diagnoses are unclear after the initial ED evaluation and who will benefit from further evaluation during observation. They are admitted if found to have a serious disease or otherwise released home. The second group is patients with selected emergency conditions for whom the diagnosis is not in doubt but an additional period of treatment or observation is deemed necessary.

---

**THE OBSERVATION APPROACH**

The traditional ED encounter lasts 2 or 3 hours. The emergency clinician performs a history and physical examination, orders laboratory and radiologic tests, and provides short-term care. When the test results return, the emergency clinician admits the patient to the hospital or discharges the patient home. The observation approach adds a third option at the completion of the ED evaluation. Additional time allows for further treatment and diagnostics. After the observation period, patients are then admitted to the hospital or discharged home.

Observation begins with the emergency clinician writing the observation orders, which include an order to “assign to observation” or “place in observation”; this order begins the observation visit. The patient is transferred to the observation unit from the main ED. An observation unit chart is started with treatment, and investigations are begun. The initial observation documentation also includes a note with the clinical impression, reason for observation, therapeutic evaluation plan, expected outcome, criteria and time frame for disposition, and health care provider responsible for the patient’s care and disposition. The responsible provider may be the emergency clinician, patient’s private physician, or a consultant.

Adequate staffing of the observation unit is crucial for the success of the program. The amount of nursing staff required is proportional to the type and intensity of treatments offered, number of beds, and patient acuity. The average staff to patient ratio is one registered nurse per four to six patients.

Staff nursing skills should be broad-based and include the ability to care for patients of all ages seen in the ED with a wide spectrum of conditions. They should have the ability to provide critical care when needed and perform on-demand phlebotomy and frequent assessments of patients under their care. Nurses should also be able to provide prolonged patient and family interactions, including hygiene care, meals, and emotional support. These skills are typically present in emergency nurses, who are optimal for observation services. When nonemergency nurses are recruited for the observation unit, they should be cross-trained, serving some shifts each month in the ED to develop the appropriate skill set to care for complex observation patients.

Additional emergency clinician staffing is also required for the observation unit. Managing ED patients in the observation unit for an additional 12 to 14 hours requires a doubling of the emergency clinician service for a single patient. Calculations of staffing for the amount of additional services amounts to approximately one full-time equivalent for every 2000 patients observed per year. In a model where the emergency clinician rounds on observation unit patients prior to an ED shift, about 6 to 9 minutes are needed per patient (ie, 60–90 minutes for a 10-bed unit, depending on patient complexity). As with the nurses,
emergency clinicians in the observation unit must have broad-based knowledge and experience in the management of a wide variety of disease processes. In a closed unit, wherein all patients first pass through the ED and care is continued by emergency medicine staff, the emergency clinician is ultimately responsible for the care of the patient and needs to provide clear leadership at all times.

Patients and staff involved in the observation process should be well informed about the goals and benefits provided by the extended service. Well-written, condition-specific, observation protocols ensure a continuum of care, including the transfer of patient care at shift change. The services provided in an ED observation unit are equivalent to inpatient services, albeit at an accelerated pace. Consultants must be available to the observation unit as they would to any inpatient service, and agreements with consulting services may be made to expedite consultations to avoid admission. The amount and type of ancillary personnel needed to staff an observation unit depend on the size and type of services offered in the unit. Most units require clerks and secretaries, medical assistants to assist nursing staff, and respiratory therapists. Observation units that offer chest pain or psychiatric evaluation may also good candidates for observation, such as immunocompromised patients, pregnant women, and patients at the extremes of age.

The structure of the observation unit will determine its clinical effectiveness and financial viability. Models for the structure of the observation unit have been described in the American College of Emergency Physicians textbook, Emergency Department Design. An observation unit that is properly designed and located within or adjacent to the ED will create large cost savings compared with traditional hospital admission while providing equivalent or improved quality of patient care in less time.

**Box e6.1**

**Conditions Appropriate for Observation**

**EVALUATION: CRITICAL DIAGNOSTIC SYNDROMES**
- Abdominal pain
- Back pain
- Chest pain
- Deep venous thrombosis
- Gastrointestinal bleed
- Syncope
- Trauma
  - Blunt abdominal
  - Blunt chest
  - Penetrating abdominal
  - Penetrating chest
  - Head injury

**TREATMENT: EMERGENCY CONDITIONS**
- Allergic reaction
- Asthma
- Atrial fibrillation
- Congestive heart failure
- Dehydration
- Headache
- Renal colic
- Infections
  - Cellulitis
  - Pneumonia
  - Pyelonephritis

**Box e6.2**

**Observation Criteria for Abdominal Pain**

**EXCLUSIONS**
- Severe dehydration
- Hemodynamic instability
- Na < 120 mEq; Na > 155 mEq
- Concomitant acute severe medical condition (eg, acute renal failure or sepsis)
- Acute peritonitis
- Probability of discharge within 24 hours < 80%
- High or moderate probability serious dangerous disease such as acute appendicitis, bowel obstruction or perforation

**INCLUSIONS**
- Inability to control pain with oral medication
- Inability to take fluids by mouth
- Possibility patient has serious dangerous cause of symptoms
- Inability to correct symptoms
- Inability to control pain with oral medication

**Clinical Conditions**

**Evaluation of Critical Diagnostic Syndromes**

**Abdominal Pain**

**Traditional Approach.** Abdominal pain is one of the most frequent complaints seen in the ED and accounts for about 11% of all visits. The typical ED evaluation of the abdominal pain patient requires a thorough history, physical examination, and appropriate diagnostic tests. Within the short time frame of 2 or 3 hours, patients are given a provisional diagnosis and are hospitalized or sent home.

**Problem With Traditional Approach.** The ED evaluation is inadequate for many patients and, in 40% of patients, the origin of abdominal pain is never determined. Acute appendicitis is the most common abdominal surgical emergency and illustrates the inadequacies of the traditional diagnostic approach. The diagnosis of acute appendicitis is missed in 20% to 30% of cases (false-negative decisions). In addition, 20% to 30% of patients taken to surgery for acute appendicitis are found to have no abnormality (false-positive decisions). Although abdominal CT scan imaging improves emergency clinician performance in identifying patients with acute appendicitis, there has been mounting concern regarding the amount of ionizing radiation exposure to patients due to increased utilization. Also, patients with early appendicitis may have a CT scan without an obvious acute finding but also have a concerning examination, warranting additional evaluation.

**Observational Approach.** With observation, the ED evaluation can be extended beyond the initial 2- or 3-hour evaluation for selected patients (Box e6.2). After the initial history and physical examination of the patient, the emergency clinician makes an estimate of the probability—via the Alvarado score—that the patient actually has appendicitis. Patients deemed to have a low probability of disease are ideal candidates for the observational approach. Patients who are difficult to assess clinically are also good candidates for observation, such as immunocompromised patients, pregnant women, and patients at the extremes of age.
During the period of observation, the patient is usually kept NPO and hydrated via the intravenous (IV) route. Serial abdominal examinations are repeated at 4-hour intervals, and laboratory tests are repeated, as appropriate. Imaging and consultations are also arranged during this time frame. For pregnant patients, abdominal magnetic resonance imaging (MRI) may be the best imaging choice. Patients are hospitalized if they have no improvement, worsening of their clinical findings, or surgical pathology diagnosed by testing.

In addition to patients with suspected appendicitis, the evaluation and care of other patients with abdominal pain improves with observation. Patients with abdominal pain often have accompanying symptoms, such as fever, vomiting, and diarrhea, resulting in metabolic disarray and dehydration. Time in observation for IV hydration and medications (eg, antiemetics, opioids), with repeat laboratory tests, provides the necessary time for the patient to recover and transition to an oral regimen of nutrition and medications prior to discharge. Consultation with the general surgery and/or gastroenterology service may be helpful in select cases. Advanced imaging, typically out of scope for an emergency department visit, can also be performed—for example, magnetic resonance cholangiopancreatochemistry or hepatobiliary scintigraphy in patients with suspected biliary pathology. Trending laboratory tests also provide an opportunity to assess whether the patient is responding to treatments appropriately versus experiencing a progressive course of illness necessitating inpatient care. Providers should be cautious of using the observation unit for patients with acute on chronic abdominal pain because the time frame and available resources of a typical observation unit stay are unlikely to address the needs of these patients sufficiently.

Chest Pain

Traditional Approach. The role of the emergency clinician in evaluating chest pain patients is twofold: (1) assessment of the probability that the patient has an acute myocardial infarction (AMI) or acute coronary ischemia (ACI); and (2) assessment of the risk of the patient having a life-threatening event. These two assessments help determine the appropriate setting for further testing and monitoring. The probability of AMI is traditionally assessed in the ED with a history, physical examination, electrocardiogram (ECG), and initial measurement of cardiac biomarkers. Patients with clear evidence of AMI based on their history and ECG are potential candidates for immediate reperfusion therapy with thrombolysis or emergency angioplasty. Such patients are at risk for life-threatening events and are best managed in the coronary care unit. Depending on the evaluating emergency clinician’s threshold, chest pain patients without definite evidence of AMI at initial evaluation are traditionally admitted to the hospital to confirm or exclude (rule in or rule out) ACI or AMI. Patients who are judged to have a low probability of ACI after the initial evaluation are released home for outpatient follow-up.

Problem With Traditional Approach. The poor performance of initial diagnostic testing makes the evaluation of chest pain highly dependent on clinical judgment. The initial ECG is diagnostic in only 50% of AMI patients, and the initial biomarker measurement has a sensitivity of only 35%. Reliance on physician judgment and initial ECG testing has resulted in as many as 2% to 5% of AMI or ACI patients being discharged home with inadvertent reassurance. The consequences of a missed AMI are significant. AMI patients not identified at the initial evaluation and released from the ED have up to a 25% risk of poor outcome. To avoid inadvertently releasing AMI or ACI patients, emergency clinicians often err on the side of admitting patients to the hospital, many who do not have an AMI or ACI. The increased sensitivity of a more liberal admission policy results in two-thirds of patients admitted for chest pain having a noncardiac cause for their symptoms, costing billions of dollars for these negative evaluation hospitalizations. Yet, despite this approach, missed AMI is the leading cause for malpractice suits against emergency clinicians.

Observational Approach. The emergency clinician can use the observation unit to extend the evaluation of selected patients with chest pain (Box e6.3). When used principally for such a purpose, the observation unit has been termed a chest pain unit. The chest pain unit has been successful in improving the sensitivity and specificity of the evaluation process and reducing unnecessary hospital admissions. Patients with a low and intermediate risk of AMI may be treated in the observation unit. Patients unsuitable for observation unit evaluation include those who have a high probability of acute myocardial ischemia, unstable vital signs, electrocardiographic findings of AMI, or persistent chest pain consistent with unstable angina.

The emergency clinician may identify patients with a low or intermediate probability for ACI by using one or more risk stratification tools. Most validated risk stratification tools widely used today incorporate some elements of risk factors, age, chest pain history, electrocardiographic findings, and troponin results. For example, the HEART score incorporates these elements and has performed well in subsequent validation studies (ie, negative predictive value > 98% for those with a low-risk score; Table e6.1).8

Patients assigned to the observation unit are first evaluated to rule out a myocardial infarction. They are serially tested with cardiac markers and ECGs. Conventional troponin level measurement on arrival and 6 hours after symptom onset is routine; with new, highly sensitive troponin assays currently available outside the United States. This time frame is accelerated in low-risk patients. Recent evidence has suggested accelerated diagnostic protocols, such as a 2- or 3-hour repeat conventional troponin level assay without provocative stress testing may be appropriate for patients deemed low risk via a validated risk stratification tool, with undetectable troponins and nonischemic ECGs.10,12

Patients are monitored with continuous electrocardiographic monitors equipped with dysrhythmia alarms and memory storage capabilities. Low-risk patients and those who are pain-free do not require continuous telemetry. However, in higher risk patients or those with ongoing pain, continuous monitoring can detect dynamic ST segment changes indicative of ischemia, which, when

**BOX e6.3**

**Observation Criteria for Chest Pain***

***EXCLUSIONS:***
- Diagnostic electrocardiographic changes or cardiac biomarkers consistent with acute myocardial injury
- High probability of serious dangerous disease or risk of adverse event
- Unstable vital signs

***INCLUSIONS:***
- Atraumatic chest pain
- Low to intermediate probability of serious dangerous disease or risk of adverse events
- Stable vital signs

*NOTE: These criteria are based on our observation protocols.
*Any criterion indicates too high a risk for observation but patient should be admitted.
*Appropriate to refer to observation if patient meets all criteria.
Deep Vein Thrombosis

Traditional Approach. The primary objectives for the treatment of deep vein thrombosis (DVT) are to prevent pulmonary embolism (PE), reduce morbidity, and prevent or minimize the risk of developing postphlebitic syndrome. Patients with suspected DVT are usually hospitalized when diagnostic testing is unavailable in the ED, or the diagnosis has been confirmed and further management is required. Traditionally, anticoagulation with unfractionated heparin has been administered by continuous IV infusion for 5 to 7 days while oral anticoagulation is instituted.

Problem With Traditional Approach. New modalities for investigation and treatment have made it possible to manage DVT on an outpatient basis with lower costs rather than with hospitalization. There are newer, less invasive investigative tests and newer therapeutic agents that do not require monitoring of coagulation profiles.

Observational Approach. Observation units can be used to arrange diagnostic studies and initiate patient treatment and education. Patients often present during the night or on weekends when definitive tests for DVT (eg, Doppler ultrasonography) may not be available. The patient may have a positive D-dimer test finding, which requires a confirmatory definitive test in intermediate- to high-risk patients because of its poor specificity. In these circumstances, the patient can be anticoagulated for the short term with one dose of low-molecular-weight heparin (LMWH; eg, enoxaparin, 1 mg/kg SQ bid) or a novel oral anticoagulant (eg, rivaroxaban, 15 mg PO bid) until the diagnosis can be clarified. If the diagnosis is confirmed, the patient can be admitted or treated as an outpatient based on hospital protocol. Patients considered for outpatient management are instructed on how to administer the medication. They are educated about DVT and the possible complications and side effects of anticoagulation therapy. This approach has been shown to result in patients spending 67% less time in the hospital and having greater physical activity and social functioning than their standard heparin cohorts. Outpatient management is not recommended if the patient has proven or suspected concomitant high-risk pulmonary embolism, significant comorbidities, extensive iliofemoral DVT, active bleeding, renal failure, or poor follow-up compliance.

Upper Gastrointestinal Bleeding

Traditional Approach. Most patients with upper gastrointestinal bleeding (UGIB) are admitted to the hospital after initial ED assessment and stabilization.

Problem With Traditional Approach. UGIB is a common and potentially life-threatening condition, with an overall mortality rate of 6% to 10%. However, most cases of UGIB are self-limited, and 80% of patients have only one bleeding episode.

Observational Approach. Many patients with UGIB can be managed in an outpatient setting, although patients at high risk for further bleeding must be identified and monitored closely. Prognostic indicators include age, heart rate, systolic blood pressure, orthostatic changes in blood pressure or pulse, color of stool or emesis, anticoagulant use, and comorbid conditions. In an attempt to refine diagnostic accuracy, risk assessment, and disposition, several scoring systems have been developed. Some practitioners use hemodynamic stability, intensity of bleeding, and underlying health status as predictors of rebleeding, need for surgery, and mortality. Admitting patients to an observation setting with early endoscopy can identify patients who can be

Deep Vein Thrombosis

Traditional Approach. The primary objectives for the treatment of deep vein thrombosis (DVT) are to prevent pulmonary embolism (PE), reduce morbidity, and prevent or minimize the risk of developing postphlebitic syndrome. Patients with suspected DVT are usually hospitalized when diagnostic testing is unavailable in the ED, or the diagnosis has been confirmed and further management is required. Traditionally, anticoagulation with unfractionated heparin has been administered by continuous IV infusion for 5 to 7 days while oral anticoagulation is instituted.

Problem With Traditional Approach. New modalities for investigation and treatment have made it possible to manage DVT on an outpatient basis with lower costs rather than with hospitalization. There are newer, less invasive investigative tests and newer therapeutic agents that do not require monitoring of coagulation profiles.

Observational Approach. Observation units can be used to arrange diagnostic studies and initiate patient treatment and education. Patients often present during the night or on weekends when definitive tests for DVT (eg, Doppler ultrasonography) may not be available. The patient may have a positive D-dimer test finding, which requires a confirmatory definitive test in intermediate- to high-risk patients because of its poor specificity. In these circumstances, the patient can be anticoagulated for the short term with one dose of low-molecular-weight heparin (LMWH; eg, enoxaparin, 1 mg/kg SQ bid) or a novel oral anticoagulant (eg, rivaroxaban, 15 mg PO bid) until the diagnosis can be clarified. If the diagnosis is confirmed, the patient can be admitted or treated as an outpatient based on hospital protocol. Patients considered for outpatient management are instructed on how to administer the medication. They are educated about DVT and the possible complications and side effects of anticoagulation therapy. This approach has been shown to result in patients spending 67% less time in the hospital and having greater physical activity and social functioning than their standard heparin cohorts. Outpatient management is not recommended if the patient has proven or suspected concomitant high-risk pulmonary embolism, significant comorbidities, extensive iliofemoral DVT, active bleeding, renal failure, or poor follow-up compliance.

Upper Gastrointestinal Bleeding

Traditional Approach. Most patients with upper gastrointestinal bleeding (UGIB) are admitted to the hospital after initial ED assessment and stabilization.

Problem With Traditional Approach. UGIB is a common and potentially life-threatening condition, with an overall mortality rate of 6% to 10%. However, most cases of UGIB are self-limited, and 80% of patients have only one bleeding episode.

Observational Approach. Many patients with UGIB can be managed in an outpatient setting, although patients at high risk for further bleeding must be identified and monitored closely. Prognostic indicators include age, heart rate, systolic blood pressure, orthostatic changes in blood pressure or pulse, color of stool or emesis, anticoagulant use, and comorbid conditions. In an attempt to refine diagnostic accuracy, risk assessment, and disposition, several scoring systems have been developed. Some practitioners use hemodynamic stability, intensity of bleeding, and underlying health status as predictors of rebleeding, need for surgery, and mortality. Admitting patients to an observation setting with early endoscopy can identify patients who can be
discharged early. Patients found to have clean-based ulcers at endoscopy have a rebleeding rate of less than 2%, almost never require urgent intervention for recurrent bleeding, and can be released. Use of this approach has been proven to be safe and cost-effective.

**Syncope**

**Traditional Approach.** Syncope is caused by a wide spectrum of disease entities. ED evaluation includes a thorough history, physical examination, and electrocardiography. Patients with evidence of possible myocardial ischemia or cardiac cause of their syncope are usually admitted to the hospital because cardiac syncope has a high risk of death—up to one-third will have a poor outcome. On the other hand, patients with noncardiac syncope have a low risk of adverse events (<1%) and can be managed as outpatients.

**Problem With Traditional Approach.** Attempts to exclude a possible cardiac cause for syncope usually result in 25% to 40% of patients being hospitalized for further evaluation and management. The traditional ED evaluation identifies only 50% of patients with a serious cause of their syncope, which often results in high rates of hospitalization. Up to one-third of patients admitted after their ED evaluation are at very low risk of an adverse event (<2%) and would be appropriate for outpatient observation evaluation.

**Observational Approach.** Extending the ED care with a period of observation for select patients with syncope is a useful strategy to reduce unnecessary hospitalizations (Box e6.4). Patients with cardiac syncope have a poor prognosis and need to be identified with a high degree of sensitivity. Prolonged telemetry monitoring can point to a specific cause in up to 20% of patients, with 50% of all abnormalities detected in the first 24 hours. The challenge for the emergency clinician is to risk-stratify patients into very low risk, who can be discharged home, intermediate risk, who are appropriate for outpatient observation, and high risk, who are appropriate for acute care hospitalization. Many factors have been found to correlate with adverse outcomes and should be considered in risk stratification; however, attempts to create simple, highly reliable decision rules have not been successful. The 1-year risk of dysrhythmia or death in syncope patients correlates with four factors: an abnormal ECG, history of ventricular dysrhythmia, history of heart failure, and age older than 45 years. Patients with none of these risk factors have only a 4.4% rate of adverse events at 1 year and may be appropriate for outpatient evaluation. In contrast, patients with three or four risk factors have a 58% adverse outcome rate and should be admitted to the hospital. Patients with one or two risk factors have intermediate risk and may be appropriate for outpatient evaluation with observation. The San Francisco syncope rule has been found to be sensitive for identifying patients who are at immediate risk for serious outcomes within 7 days, with ranges in different studies from 74% to 96%. Its criteria are the absence of abnormal electrocardiographic findings, history of CHF, dyspnea, hematocrit level of less than 30%, or hypotension.

The **Risk stratification Of Syncope in the Emergency Department (ROSE) criteria** suggest that an elevated B-type natriuretic peptide (BNP) level, hemoccult-positive stool, anemia, low oxygen saturation, and presence of Q waves on the ECG predict serious outcomes at 30 days. These rules had an 87% sensitivity and 98.5% negative predictive value to help risk stratify patients. In this study, the isolated finding of BNP greater than 300 pg/mL was a major predictor of serious outcomes and was present in 89% of patients who died within 30 days. In another study, it was found that 6.1% of patients have severe outcomes within 10 days of syncope evaluation. The mortality rate was 0.7%, and 5.4% of patients were readmitted or experienced major therapeutic intervention. Risk factors associated with severe short-term outcomes included abnormal ECG, history of CHF, age older than 65 years, male gender, history of chronic obstructive pulmonary disease, structural heart disease, presence of trauma, and lack of prodromal symptoms.

The **Evaluation of Guidelines in SYncope Study 2 (EGSYS 2)** prospectively followed nearly 400 patients at 1 month and 2 years. The death rate was 2% at 1 month and 9% at 2 years. Patients with advancing age, presence of structural heart disease, and/or an abnormal ECG had higher risk. Additional factors that would indicate a patient should be admitted rather than placed in outpatient observation include history of ventricular arrhythmia, low left ejection fraction, abnormal neurologic findings, positive cardiac biomarkers, and loss of consciousness for longer than 15 minutes.

Because there are many factors that could be considered in the emergency clinician’s risk stratification for patient disposition to observation or acute hospitalization (see Box e6.4), the best practice approach is to come to an institutional consensus on this risk stratification and codify this consensus in a syncope order set. This approach reduces health care provider variability in decision making by adopting evidence-based practices more uniformly, which improves the quality of patient care and use of health care resources.

During the observation period, serial examination of patients is carried out, including vital signs, with most patients safely discharged home without hospitalization. Continuous telemetry, consultation, serial cardiac enzyme level assays for those with a concern for AMI, and further tests, such as two-dimensional echography of the heart, should be arranged, when appropriate. The period of observation can also identify patients with cardiac dysrhythmias or sinus pauses who are candidates for more extensive diagnostic evaluation in the hospital. Typically, a 12-hour minimum duration of telemetry is used to evaluate a syncope patient in an observation unit, with longer monitoring more

---

**BOX e6.4: Observation Criteria for Syncope**

**EXCLUSIONS**
- History of dyspnea or loss of consciousness >10 min or seizure
- Past history of ventricular dysrhythmia
- Abnormal laboratory hematocrit level <30%
- Elevated B-type natriuretic peptide (BNP) or pro-BNP, or positive cardiac biomarkers
- Evidence of injury or ischemia on ECG or documented or highly suspected unstable dysrhythmia
- Low oxygen saturation or unstable vital signs
- Evidence of clinically significant gastrointestinal hemorrhage (ie, stool positive for blood in the setting of hemocrit drop)
- New focal neurologic findings or persistently altered mental status
- High or moderate probability of serious dangerous disease or adverse event
- History of low ejection fraction (eg, <30%)
- Clearly vasovagal episode (ie, candidate for immediate discharge home)

**INCLUSIONS**
- Possibility of pathologic cause of the syncope
- Intermediate probability of serious dangerous disease or adverse event

*NOTE: These criteria are based on our observation protocols.*

*Any criterion indicates too high a risk for observation but patient should be admitted.*

*Appropriate to refer to observation if patient meets all criteria.*
Transient Ischemic Attack

Traditional Approach. More than 300,000 people suffer a transient ischemic attack (TIA) each year. For most patients, it is a transient event that will not recur if they take one aspirin each day. However, for 1 in 10 patients, it is a warning sign that they will suffer a stroke unless they are appropriately evaluated and treated. Traditionally, the patient is assessed in the ED with history, physical examination, laboratory tests, electrocardiography, and head CT scan. Most patients are then hospitalized for serial clinical evaluations, neurology consultation, carotid imaging, echocardiography, and cardiac monitoring.

Problem With Traditional Approach. The problem with the traditional approach is that most TIA patients are admitted primarily for expedited evaluation. After 3 days of evaluation, few will be found to have clinically significant carotid stenosis or structural heart disease requiring an intervention. As a result, there is a significant opportunity to develop a more cost-effective approach for the evaluation of TIA.

Observational Approach. Observation is an alternative to hospitalization for TIA patients with a negative ED evaluation for whom the emergency clinician still has concern. Currently, the ABCD² score is a validated risk-stratification tool that can help identity those patients most appropriate for an observation unit protocol (Table e6.2). Risk-stratification of TIA patients is discussed in Chapter 91. Patients at highest risk (ie, a score of 6 or 7) should be managed as inpatients, whereas intermediate- and low-risk patients are candidates for observation. This approach has been shown to decrease the cost of evaluation and has not resulted in adverse patient outcomes versus standard inpatient care.

**ABCd² Score for Risk Stratification in Transient Ischemic Attack**

Trauma

There are more than 41 million trauma-related ED visits annually. Patients with serious injuries require hospitalization for definitive therapy, whereas those with minor injuries can be discharged after treatment in the ED.

The problem with the traditional ED approach is that many patients have injury patterns or actual injuries that fall somewhere between the two scenarios just described. If these patients are released home, there is a risk that some will have poor outcomes as a result of missed injuries. On the other hand, because most of these patients do not have serious injuries, admitting this group to the hospital will result in a waste of scarce health care resources.

Observation units have been found to be an efficient and useful strategy for the evaluation and management of trauma victims. With observation, select patients can be evaluated further to determine the need for admission.

Blunt Abdominal Injury

**Traditional Approach.** Current ED management of blunt abdominal trauma (BAT) patients includes history taking, physical examination, blood analysis, plain radiography, bedside ultrasonography, and CT scanning. After initial stabilization and exclusion of other major injuries in the ED, most patients suffering BAT are admitted to the hospital for further evaluation and monitoring.

Problem With Traditional Approach. The initial evaluation is inadequate for the accurate disposition of many BAT patients. One-third of patients who do not have any symptoms or signs suggestive of intra-abdominal injury may actually have significant injury. Also, because none of the present modalities for investigating the presence of injury is 100% sensitive, many patients with initially negative investigations are hospitalized.

Observational Approach. BAT patients appropriate for observation include those who, after initial evaluation, have no clear evidence of serious injury on physical examination but remain at risk for serious injury because of the mechanism of the injury or his or her personal health (eg, anticoagulant use). Evaluations during an observation unit stay may include repeat physical examinations, laboratory testing, imaging, and specialty consultations. Patients are hospitalized if their condition deteriorates during the observation period or if, after testing, they are found to have serious internal injury. CT alone is not adequate to rule out serious injury, with a sensitivity of only 80% to 95%. Observation alone in patients with BAT is not sufficient because up to 20% of patients with significant injury will not have abdominal tenderness or will develop it even after a short period of observation. Thus, the prudent approach to patients with significant BAT without clear evidence of intra-abdominal injury is the use of a diagnostic test, such as CT, together with a period of observation.

Penetrating Abdominal Injury

**Traditional Approach.** Most patients with penetrating abdominal injury are hospitalized for further evaluation, which may include wound exploration in the operating room and additional diagnostic testing.

Problem With Traditional Approach. Many of these hospitalizations are unnecessary because only two-thirds of patients with abdominal stab wounds have a breach of the peritoneum, and two-thirds of them do not sustain visceral injury.

Observational Approach. A period of observation can identify patients who do not require surgical intervention. Patients undergo serial examinations by the emergency clinician, further diagnostic testing, and specialty consultation. Those without evidence of peritoneal perforation or visceral injury after evaluation are sent home after proper wound care.
The conservative approach to penetrating abdominal wounds was developed in the 1970s. Those without peritoneal breach can be safely sent home after wound care and a period of observation, without the need for hospitalization. Those with stab wounds to the abdomen with peritoneal breach but a negative finding on diagnostic laparoscopy or imaging with CT or ultrasonography can be safely managed in an observation unit. Patients with significant intra-abdominal injuries identified during observation are admitted; the 70% to 90% of patients without such injuries are released home. Gunshot wounds are often more difficult to evaluate than stab wounds and usually require admission.

Blunt Chest Trauma

**Traditional Approach.** Many patients who have a history of blunt chest trauma (BCT) in high-velocity accidents are admitted to the hospital to rule out myocardial or pulmonary contusion. Patients with isolated BCT who are otherwise stable, with a normal ECG, are suitable for a period of observation to exclude myocardial injury. During the period of observation, patients are monitored with continuous ECG, specifically assessing for dysrhythmias. Serial cardiac enzyme determinations, such as troponin level, are also carried out to detect evidence of myocardial injury. Patients with sternal fractures or other evidence of a higher risk of intrathoracic injury should be considered for transesophageal echocardiography. Those with negative evaluations during the period of observation are released home for outpatient follow-up.

Much of the period of observation in patients with BCT focuses on identifying the presence and prognosis of myocardial contusions. The overall incidence of cardiac-related complications in these patients is low (0.1%). Patients with blunt cardiac trauma who have complications usually have an abnormal ECG or abnormal troponin level at presentation. Conversely, normal ECG and troponin levels correlate with the lack of clinically significant complications. Patients who have isolated chest wall contusions and no abnormality of serial troponin levels, electrocardiographic abnormalities, or dysrhythmia during 6 to 12 hours of electrocardiographic monitoring are unlikely to have complications.

**Penetrating Chest Injury**

**Traditional Approach.** Patients with penetrating chest injury present with a spectrum of severity, ranging from a severe life-threatening injury requiring urgent operative intervention to hemodynamically stable patients with a negative initial evaluation. Most patients presenting with penetrating chest injuries are admitted to the hospital to exclude serious injury to the heart, lungs, and major blood vessels.

**Problem With Traditional Approach.** The accuracy of this approach is limited because many patients with evidence of injury are admitted but have no further deterioration or need for medical therapy. On the other hand, there are those without obvious evidence of serious injury who will have a negative outcome if released after the initial evaluation.

**Observational Approach.** A period of observation combined with diagnostic imaging can improve clinical decision making. Patients with evidence of a small pneumothorax or hemothorax can be monitored for deterioration. Those without evidence of serious injury but of concern to the emergency clinician can likewise be observed for complications. During the period of observation, patients are monitored for respiratory or hemodynamic compromise. Repeat chest radiographs can detect the development of hemothorax or pneumothorax. Patients who deteriorate during the period of observation require hospitalization.

The safety and efficacy of managing asymptomatic stab wound victims in the short-term observation unit have been clearly established. A total of 5% to 15% will require hospitalization because of the development of delayed pneumothorax, subcutaneous emphysema, hematoma, or pneumopericardium. In addition, most stab wound victims with small pneumothoraces or hemothoraces will be treated solely with a chest tube, without further surgical intervention. Major trauma centers can manage many of these patients as outpatients without hospitalization by using a period of observation.

Patients with penetrating wounds to the cardiac area of the chest (between the nipples), region of the great vessels, or thoracoabdominal area usually require more intensive testing to exclude injury not only to the heart, major vessels, and lungs but also to the diaphragm and abdominal organs. Echocardiography may detect pericardial fluid or tamponade in patients with penetrating injury in close proximity to the heart. Patients with small effusions may be observed in a monitored setting with serial examinations, whereas patients with large effusions should be treated surgically. Patients with a negative echocardiogram can be observed in the observation unit. Even patients with small effusions may have sustained a serious injury, so the intensity of monitoring needs to be high.

**Treatment of Emergency Conditions**

**Asthma**

**Traditional Approach.** More than 25 million people in the United States are afflicted with asthma. Acute exacerbation of asthma is a common ED presentation, with estimated annual inpatient admissions with asthma listed as a primary discharge diagnosis exceeding 450,000.22 Traditionally, therapy has been provided in the ED for 2 to 4 hours, consistent with national guidelines.23 The initial assessment includes history, physical examination, oxygen saturation, and peak expiratory flow rate (PEFR) or forced expiratory volume in 1 minute. Treatment consists of beta agonists, magnesium sulfate, and steroids, where appropriate. Patients who do not improve after 3 or 4 hours of treatment are hospitalized for further management.

**Problems With Traditional Approach.** With this approach, one-third of patients are hospitalized. This translates into an estimated medical cost of $2.5 billion annually. Another pitfall in the traditional ED treatment of asthma is that short encounters times do not allow for identification and aggressive treatment of patients with a higher tendency for relapse. This leads to repeat ED visits, additional medical costs, and diminished quality of life.

**Observational Approach.** An alternative to hospitalization for patients failing ED treatment is the use of an extended, short-term intensive protocol for 8 to 12 hours in an observation unit for select patients (Box e6.5). With extended treatment, 80% of such patients can be discharged home. Inclusion criteria for observation unit management are failure of standard initial management with continued respiratory distress and a reasonable response to initial management. An increased risk of relapse is indicated by a history of numerous asthma-related ED or clinic visits within the past year, using more outpatient medications (including home nebulizers), and longer duration of symptoms. Exclusion criteria for observation include unstable vital signs, evidence of impending respiratory failure (increased work of breathing or evidence of fatigue), or severe airway restriction (PEFR < 80 L/min after first inhaled beta agonist treatment). Also considered during selection for observation are factors that correlate with unsuccessful treatment during observation. These
include a previous ED visit in the past 10 days, previous intensive care unit admission or intubation, hospitalization during the previous year, three or more ED visits in the past 6 months, use of oral steroids for more than half of the previous year, and peak flow after the third beta agonist treatment that is less than 32% of predicted.

Therapy in the observation unit is a continuation of ED treatment with nebulized beta agonists every 2 to 4 hours and repeated ipratropium at 6 hours after initial therapy. Intravenous magnesium is another useful treatment in this patient population. Patients are released from the observation unit when they are not in respiratory distress, have minimal residual symptoms, and have a PEFR of 70% or higher of predicted or personal best. Before discharge, there should also be patient educational activities and assessment of inhaler techniques. Patients should be initiated into follow-up monitoring should also be arranged.

Observation unit patients also reported fewer problems with care received, communication, emotional support, physical comfort, and special needs. Observation has also been shown to have value in the management of pediatric patients with asthma. Of those who would otherwise require hospitalization, 30% to 70% can be successfully managed as outpatients with the observation unit.

**Atrial Fibrillation**

**Traditional Approach.** Atrial fibrillation is a relatively common condition that occurs in less than 3% of adults and is the most common sustained cardiac dysrhythmia in patients presenting to the ED. The goals for the management of acute atrial fibrillation are hemodynamic stabilization, symptom relief, prevention of thromboembolism, resolution of the dysrhythmia, and exclusion of serious pathologic causes of the dysrhythmia. Most patients who present to the ED with new-onset atrial fibrillation or acute atrial fibrillation are hospitalized.²⁴

**Problem With Traditional Approach.** Recently, the necessity of admitting most patients with acute atrial fibrillation has been questioned.²⁵,²⁶ It is recognized that new-onset atrial fibrillation for most patients is a transient dysrhythmia, with no serious precipitants and a benign prognosis. One retrospective analysis of 216 patients admitted for atrial fibrillation found that one-third of patients did not actually require admission to the hospital.²⁷

**Observational Approach.** The observational approach to new and acute atrial fibrillation has been validated in a number of clinical trials. The period of observation is usually 8 to 12 hours. During observation, patients are treated to correct their dysrhythmia and evaluated for serious precipitants of their condition. After observation, 80% to 90% of patients can be discharged home without hospitalization.

For select patients (Box e6.6), observation extends the ED evaluation of the patient for serious underlying medical conditions that may have precipitated the arrhythmia, such as AMI or hyperthyroidism. AMI is excluded as a precipitant with serial electrocardiographic and cardiac biomarker testing on arrivals and 6 hours later and an evaluation for unstable angina in the subset of patients with a presentation that raises concern for AMI (ie, chest pain). The period of observation is also used to detect structural heart disease with the use of echocardiography, where appropriate. Patients are excluded from observation if they exhibit hemodynamic instability, comorbid conditions, heart failure, or evidence of active coronary artery disease.

Observation is also used to extend the treatment period of the patient with atrial fibrillation. The spontaneous conversion rate for patients with acute atrial fibrillation is 50% to 70% within the first 24 hours. Patients who spontaneously convert have a low rate of structural heart disease. Those who present within a clear, 48-hour time of onset but do not spontaneously convert in the first 8 hours can be converted chemically or electrically. After cardioversion, the patient needs to be observed. This is especially true for patients converted with the newer class III antidysrhythmic agents (eg, ibutilide), which have the potential for serious side effects, such as torsades de pointes (5% of patients), sinus brady-cardia, and sinus arrest. Currently, the CHADS² score is used to determine the need for anticoagulation in patients discharged home after a cardioversion to normal sinus rhythm in the ED or observation unit (Table e6.3). Those with a score of 2 or higher

### Observation Criteria for Asthma

#### INCLUSIONS
- Shortness of breath
- Mild to moderate use of accessory muscles
- Wheezing
- Fair to good air exchange
- Stable vital signs
- Normal mentation

#### EXCLUSIONS
- Respiratory fatigue or failure (respiratory rate > 40 breaths/min, oximetry < 90%)
- Inability to perform spirometry or peak flows
- Peak flow after third beta agonist <30% of predicted
- Concomitant illness (eg, pneumonia, heart failure)
- Bronchospasm due to aspiration or foreign body
- Temperature > 38.3° C (101°F)
- Need for continuous nebulizer treatment, BiPAP, or heliox
- Acute ischemic electrocardiographic changes or positive cardiac biomarkers

#### NOTE: These criteria are based on our observation protocols.

#### Observation Criteria for New-Onset Atrial Fibrillation

#### INCLUSIONS
- Low probability of serious dangerous disease or risk of adverse event
- Stable vital signs

#### EXCLUSIONS
- High or moderate probability of serious dangerous disease or adverse event
- Evidence of injury or ischemia on ECG or documented or highly suspected unstable dysrhythmia
- Low oxygen saturation or unstable vital signs
- New focal neurologic findings or persistently altered mental status
- Poor candidate for outpatient anticoagulation
should be started on an anticoagulant (ie, LMWH or factor Xa inhibitor), except for those with a contraindication to anticoagulation (ie, fall risk). \(^2\) All patients managed with rate control alone and discharged while still in atrial fibrillation should be anticoagulated, barring contraindications. The outpatient follow-up and anticoagulation plan should be closely coordinated with the patient’s outpatient providers.

**Congestive Heart Failure**

**Traditional Approach.** Patients who present to the ED with CHF undergo history taking, physical examination, and investigations, including chest radiography. Treatment is begun with oxygenation, diuretics, inotropic agents, and vasodilators, where appropriate. Most CHF patients treated in the ED are eventually hospitalized.

**Problem With Traditional Approach.** CHF is highly prevalent, affecting approximately 1% of people in their 50s and increasing progressively with age to afflict 10% of people in their 80s. It is an increasing problem; over 5 million Americans have the disease, and 550,000 new cases are diagnosed each year.\(^2\) One-third of patients with CHF require hospitalization each year, and 500,000 new cases are diagnosed each year.\(^2\) One-third get readmitted each year, and one-third die within 2 years. The annual cost to the health care system of managing patients with heart failure admitted to the hospital has been estimated at $32 billion.\(^10\) Between 80% and 87% of patients diagnosed with CHF are hospitalized.\(^29\)

**Observational Approach.** Observation is a strategy to avoid hospital admission of patients with CHF, which results in cost savings. Selected patients can be safely managed in an observation unit (Box e6.7). Such patients include those with a high probability of successful treatment with short-term extension of the ED visit. Patients should also have a low severity of illness. They should not be hypoxic, have pulmonary edema or hypotension, and have objective evidence of AMI, hemodynamic instability, or serious comorbid conditions. BNP has been used to streamline decision making. Patients with BNP levels between 100 and 500 pg/mL are suitable candidates for observation unit care because a large proportion of these patients should be able to be discharged home. The test has a negative predictive value of greater than 95% and positive predictive value of 70% to 95%. It correlates with pulmonary capillary wedge pressure and because, its half-life is less than 30 minutes, serial measurements during observation can evaluate the effects of therapeutic interventions.

Therapy and evaluation are a continuation of the initial 2- or 3-hour ED visit for up to 23 hours. Continuous electrocardiographic monitoring for dysrhythmias is performed because up to 30% of CHF patients have dysrhythmias. Inotropic agents can be infused and the patient educated about preventable causes of the exacerbation. Therapy may include continuous infusion of a loop diuretic (0.05–0.1 mg/kg/hr) titrated hourly to a net fluid balance of −1 mL/kg/hr. In most patients with acute exacerbation of chronic CHF, the cause of their exacerbation is preventable, such as failure to take their medications or dietary indiscretion. The opportunity to provide patient education, medication review, and consultations with dietary and social services, where necessary, is fully used because this has been shown to improve compliance with therapy. Patients are discharged home when their symptoms are adequately controlled, all reversible causes of morbidity are treated or stabilized, and adequate outpatient support and follow-up care are arranged. With observation, the focus of ED care can shift from providing only episodic treatment for CHF patients to providing more comprehensive and preventive care. Compared with acute care hospitalization, observation has a much reduced length of stay and significantly lower costs.

**Dehydration**

**Traditional Approach.** Dehydration is often the presenting symptom of an underlying disease state and can affect the very...
Observation Criteria for Dehydration

**EXCLUSIONS**
- Severe dehydration
- Moderate or high probability of serious dangerous disease or risk of adverse event
- Unstable vital signs
- Na < 120 mEq; Na > 155 mEq
- Concomitant acute serious medical condition (eg, acute renal failure, sepsis)

**INCLUSIONS**
- Inability to correct symptoms in the emergency department during initial evaluation
- Inability to take fluids orally

*NOTE:* These criteria are based on our observation protocols.
1. Any criterion indicates too high a risk for observation but patient should be admitted.
2. Appropriate to refer to observation if patient meets all criteria.

Observation Criteria for Pneumonia

**EXCLUSIONS**
- Moderate or high probability of serious dangerous disease or risk of adverse event
- Unstable vital signs
- Risk factors for poor outcome—in immunocompromise, neuromuscular disorder, pulmonary tuberculosis, cystic fibrosis
- Health care–associated pneumonia or hospital-acquired pneumonia
- Concomitant acute serious medical condition (eg, acute renal failure, sepsis)

**INCLUSIONS**
- Stable vital signs
- Normal mentation
- Low risk by clinical judgment or severity index

*NOTE:* These criteria are based on our observation protocols.
1. Any criterion indicates too high a risk for observation but patient should be admitted.
2. Appropriate to refer to observation if patient meets all criteria.

Infections

**Pneumonia**

**Traditional Approach.** Each year, approximately 1,100,000 patients are hospitalized with pneumonia, at a cost of over $7 billion in the Medicare population alone.2231 Many of these patients are admitted after initial ED evaluation. Physicians often rely on subjective criteria such as clinical appearance when selecting patients for hospital admission.

**Problem With Traditional Approach.** There is great variation in the admission rates for pneumonia. Emergency clinicians tend to overestimate the risk of death in patients with pneumonia, which has resulted in many low-risk patients being hospitalized unnecessarily.

**Observational Approach.** Observational care is appropriate for patients with stable vital signs, normal mentation, and judged to be at low risk by clinical judgment or severity index (Box e6.9). The risk stratification of patients with pneumonia is discussed in Chapter 66. Patients who are not appropriate for observation include those who are immunocompromised or hypoxic, at risk for pulmonary tuberculosis, or suspected of having a PE (Table e6.4).

During observation, patients are treated with antibiotics, oxygen therapy, and pulse oximetry monitoring. Hydration is given orally or IV. After 10 to 12 hours of treatment in the observation unit, the patient is reevaluated, and a decision about disposition is made. Patients who deteriorate during the observation period or have an oxygen saturation of less than 90% on room air after observation should be admitted to the hospital.

**Pyelonephritis**

**Traditional Approach.** Pyelonephritis is a serious infection that frequently results in hospitalization for IV hydration and antibiotic administration.

**Problem With Traditional Approach.** Many patients with pyelonephritis are at very low risk for developing complications.

**Observational Approach.** Observation is appropriate for adult nonpregnant women who appear to have uncomplicated pyelonephritis. Patients receive an initial dose of IV antibiotic, IV fluids, antimalaric, and antipyretic. Laboratory tests include complete blood cell count, urinalysis, and urine and blood cultures. Patients who are clinically stable and able to tolerate oral fluids are released home after 12 hours of treatment.

Outpatient management of selected pyelonephritis patients with observation is safe and effective. Only 5% to 25% of patients require hospitalization after the period of observation. At a 3-week follow-up examination, 2% to 6% will have developed complications and require hospitalization. With a period of observation and careful follow-up evaluation, select patients with pyelonephritis can be successfully managed without hospital admission.
SUMMARY

Health care stakeholders will continue to demand improved outcomes at a lower cost as our current system evolves. This interest is best illustrated by Medicare’s triple aim of improving the experience of care, improving the health of populations, and reducing per capita costs of health care. Care in a dedicated observation unit meets this challenge by shifting the site of care to less resource-intensive settings and embracing evidence-based protocols. As financial and operational pressures on the health care system persist, observation services will increasingly become integrated into the ED as a standard setting and model of care in the future.

KEY CONCEPTS

- Hospitalization can often be avoided by providing short-term care (<24 hours) in observation units for certain medical disorders, such as chest pain, deep vein thrombosis (DVT), upper gastrointestinal (GI) bleeding, syncope, transient ischemic attack (TIA), trauma, asthma, atrial fibrillation, congestive heart failure (CHF), dehydration, pneumonia, and pyelonephritis.
- The use of observation units results in cost savings and improved patient satisfaction with care.
- Observation care is on an outpatient basis and is not necessarily delivered in a specific location.
- Observation is used to provide additional time for therapeutics and/or diagnostics for patients with an uncertain need for inpatient admission.
- Observation care is often influenced by payer policies and is congruent with recent national efforts to increase patient safety while also reducing unnecessary costs.
- Evidence-based observation care is delivered in a dedicated area for this purpose, using condition- or complaint-specific protocols of care.
- When used appropriately and at benchmark levels of quality and efficiency, observation visits can reduce the duration and thus the cost of hospital care for eligible patients while also reducing the incidence of unsafe discharges to home.
- The role of observation care is best studied in chest pain patients but, over the past several decades, patients with many other conditions have shown to be managed effectively using observation.
- Emergency clinicians should play a central role in identifying and managing observation patients.

REFERENCES

CHAPTER e6: QUESTIONS & ANSWERS

e6.1. Which of the following is not a high risk factor for adverse events or death in patients with a syncopal event? A. Abnormal electrocardiogram (ECG) B. Advancing age C. Female gender D. History of heart failure E. History of ventricular dysrhythmia

Answer: C. Female gender is not included in the factors to be considered in the risk stratification of patients for consideration of referral to outpatient observation for further evaluation and management of patients with syncope (see Box e6.4). Additional factors that would indicate a patient is unsuitable for observation to evaluate their syncpe episode include those who have a history of dyspnea, loss of consciousness for more than 10 minutes, trauma or seizure, past history of chronic obstructive pulmonary disease (COPD) or structural heart disease, abnormal laboratory results—hematocrit level < 30%, elevated brain natriuretic peptide (BNP) or ProBNP level, positive cardiac or abnormal electrolyte levels—electrocardiographic evidence of injury or ischemia, documented or highly suspected unstable dysrhythmia, low oxygen saturation or unstable vital signs, stoo1 positive for blood, new focal neurologic findings or persistently altered mental status, and/or high or moderate probability of serious dangerous disease or adverse event.

e6.2. Which of the following criteria, when present in a patient with chest pain and a nondiagnostic electrocardiogram (ECG), is consistent with the decision to refer a chest pain patient to outpatient observation rather than admission to the acute care hospital? A. Blunt chest trauma preceding pain B. Cocaine-induced chest pain C. History of three-vessel coronary artery bypass grafting (CABG) D. Minimal elevation in troponin E. Recurrent chest pain

Answer: B. Patients with a low risk of acute myocardial infarct (AMI) are candidates for referral to an outpatient chest pain observation unit rather than admission to the acute care hospital. Patients considered appropriate for placement in an outpatient chest pain observation unit include those with nontraumatic chest pain, low probability of disease or risk of adverse event, stable vital signs, normal cardiac biomarkers, and nondiagnostic ECG. Patients with cocaine-induced chest pain who meet the previous criteria may also be appropriately evaluated in a chest pain unit. Patients unsuitable for observation unit evaluation include those who have evidence of moderate to high risk, as shown by diagnostic electrocardiographic changes, positive cardiac biomarkers, clinical evidence of moderate or high probability of serious dangerous disease or risk of adverse event, continuing chest pain, and/ or unstable vital signs.
e6.3. Which of the following parameters by itself makes inpatient admission the recommended emergency department (ED) disposition of a patient with the diagnosis of pneumonia?
A. Age > 65 years
B. Arterial pH < 7.35
C. Presence of congestive heart failure
D. Presence of neoplastic disease
E. Sao₂ less than 90%

Answer: E. See Table e6.1 for the Pneumonia Severity Index scoring system for admission decisions. Oxygenation is the first step in determining risk and hypoxia, regardless of any other findings, justifies inpatient care.

e6.4. All the following clinical scenarios are suitable candidates for ED observation unit admission except which one?
A. Atrial fibrillation with new onset of acute on chronic congestive heart failure
B. Chest pain with low probability of serious disease or adverse event
C. Congestive heart failure with BNP level of 400 pg/mL
D. Dehydration with moderate electrolyte abnormalities
E. Hyperemesis gravidarum

Answer: A. All the choices are acceptable observation candidates except for atrial fibrillation, with new onset of acute on chronic congestive heart failure. See Box e6.6 for observation criteria for new-onset atrial fibrillation.

SUMMARY

KEY CONCEPTS

- Changing demography and an evolving culture in the United States is changing emergency medicine practice.
- Disparities in health and health care delivery continue, despite efforts to improve care. Emergency clinicians and their institutions will need to be part of the solution—treating preventable conditions that become crises because of reduced access to primary care and specialists and acting as advocates for strategic system change to eliminate disparities in their institutions.
- Emergency departments (EDs) will contribute to breaking cycles of illness if they seize opportunities to establish treatment plans and interventions that focus on social determinants of health, health literacy, and empowerment of patients to participate in their care.
- Treatment plans that are created with patients and are based on what matters to them have the greatest opportunity for success.
- Emergency clinicians will improve the quality of care provided if they can meet federal standards for culturally and linguistically appropriate care, recognizing that patients with limited English proficiency have a right to medical interpretation.
- Culturally sensitive, patient-centered, and trauma-informed care will improve patient—emergency clinician communication and satisfaction, decrease medical errors, and promote patient follow-through with recommendations.

CHAPTER e7
Multiculturalism and Care Delivery

James L. Thea | Morsal Tahouni

PRINCIPLES

In recent years, multiple high-profile incidents have put the role of multiculturalism and race in society on the forefront of public and medical discussion. These cases outline to an extent the distance that our society has come in understanding race relations but even more, delineate how much farther we have left to go. As a microcosm of the larger society, the medical institution, and by extension the practice of emergency medicine (EM), should develop a greater understanding and self-awareness of the role of multiculturalism and race in the delivery of medical care.

At baseline, the practice of emergency medicine is unique and challenging because most patients in the emergency department (ED) are unknown to providers. There is little time to establish a rapport, earn a patient’s trust, make a correct diagnosis, and develop a treatment and discharge plan designed for that patient. EM provides opportunities that can teach emergency clinicians to listen and learn what matters to people, because treatment plans created with patients and based on what matters to them have the greatest opportunity for success. There is only a brief window of opportunity to optimize the physician-patient encounter. A multicultural physician and patient population present a dual and sometimes formidable barrier when providing appropriate and equal health care access.

Every day, emergency clinicians encounter a multitude of challenging cases that can be further complicated by subtle cultural differences. Providing effective care requires an appreciation of these differences, as well as an understanding of a provider’s own biases. Lack of understanding of the role of cultural factors and provider bias can have an adverse effect on physician-patient communication and trust. Health outcomes can also be negatively affected, as demonstrated by an increasingly large body of literature on racial and ethnic disparities in interventions and health care. Race, culture, ethnicity, class, gender, economic conditions, spirituality, and sexual orientation define health and illness for patients and affect access to health care and the quality of services received. Missing these cues may lead to medical errors.1,2

The American College of Emergency Physicians (ACEP) supports cultural awareness and emergency care with policies that are updated as necessarily. These policies recognize that denial of emergency care or delay in providing emergency services on the basis of race, religion, ethnic background, social status, type of illness or injury, or ability to pay is unethical.3

The purpose of this chapter is to provide the knowledge base in cultural competence that is essential to meet patient needs, improve health outcomes, reduce racial and ethnic disparities, and achieve professional goals.

RATIONALE FOR CULTURAL COMPETENCE

Changing Demographics: New Challenges for Emergency Clinicians

Both the US population and the types of health problems seen by emergency clinicians are constantly changing. In 2010, the US Census Bureau estimated that 13.1% of the US population was foreign-born and that 21% spoke a language other than English at home.4 According to most recent census estimates, 26% of the population identifies as other than solely “white,” and 16.6% describe themselves as Hispanic or Latino.5 It is projected that the proportion of all minorities will increase significantly from 37% in 2012 to 57% by 2060, and the United States will become a majority minority nation for the first time by 2043.6

These figures do not speak to the diversity within these groups. The category Hispanic, for example, is an ethnic grouping counted in the race category of the census, but it fails to capture the significant range of diversity represented by Spanish speakers. Hispanics may share some cultural practices and speak similar versions of the Spanish language, but they have major differences in vocabulary and dialect, history, socioeconomic status, cultural identity, what they call themselves (Hispanic or Latino), levels of acculturation, health beliefs, habits, access to care, and health outcomes. The changing cultural landscape will challenge EM providers to recognize, account for, and address these differences when providing care for their patients.

Racial and Ethnic Disparities in Health Care Access and Outcomes

In the past decade, financial and nonfinancial barriers to access for racial and ethnic minority populations have been thoroughly documented. These include high rates of noninsurance, lack of prenatal care, hospitalization for ambulatory-sensitive diagnoses (an indicator of reduced access to primary care), and concentration of minorities in areas of physician shortage.7 In 2003, the Institute of Medicine (IOM) produced a report commissioned by Congress in which more than 100 studies assessing the quality of care for racial and ethnic US minorities were analyzed.8 According to the IOM report, minorities received fewer needed services and procedures than whites after control for insurance status, income, and other access factors. These findings applied to a wide range of health conditions, such as cancer, cardiovascular disease, human immunodeficiency virus (HIV) infection and AIDS, diabetes, and mental illness. The findings identified cultural and linguistic barriers, fragmentation of the health care system, and differences in site of care delivery and insurance coverage as explanatory factors. The report concluded that “racial and ethnic disparities in health care exist, and because they are associated with worse outcomes in many cases, they are unacceptable.”9

The IOM report also discussed important nonfinancial barriers to access, such as the unequal distribution of physicians in areas where minority populations live. In particular, it was noted that the number of racial and ethnic minorities living in medically underserved areas is three times the proportion of minorities in the general population. Poor urban communities with high African American and Hispanic representation, averaged 24 physicians/100,000 population compared with 69 physicians/100,000 in communities with low representation. Although minority physicians are more likely to serve patients with Medicaid or no insurance, they are still significantly
Factors Contributing to Disparities in Health Outcomes

In the past decade, reports have been regularly published in major peer-reviewed journals regarding disparities in the use of diagnostic tests and procedures, access to appropriate treatment modalities, waiting times to receive care, and length of stay in the ED. The Coalition to Reduce Racial and Ethnic Disparities in Cardiovascular Disease Outcomes, for example, has acknowledged racial and ethnic differences in cardiovascular comorbidities, use of evidence-based therapies, prolonged time to reperfusion, and a race-based invasive procedure gap for coronary intervention. Evidence from other specialties corroborates that differences in provision of medically appropriate procedures and therapies are often related to race and ethnicity; the reasons can be complex and multifactorial. Recent studies have shown that disparities in treatment and outcomes exist in areas of cancer care—screening, treatment, and outcomes. Despite decades-old identification of these differences and regardless of the setting, health care disparities remain a real and pervasive threat to patient care.

Discrimination and Health Outcomes

Deleterious health consequences that result from racial discrimination have been well documented. In states where respondents to a social survey indicated that blacks are intellectually inferior and lacked an innate ability to excel, there was an increase in age-adjusted black mortality that was considerably stronger than the correlation between mortality and socioeconomic status. Further studies found that even perceived discrimination had a significant effect on health. Mechanisms used to cope with the stress of racism have been shown to backfire by adding to health risks, such as in regard to smoking, substance abuse, and overeating. Racism-induced stress has been shown to be negatively associated with disease entities such as diabetes, hypertension, depression, and preterm birth. For example, a relationship between race consciousness and blood pressure has been shown. Findings of Brewer and colleagues have suggested that among black patients, race consciousness is associated with higher diastolic blood pressure (BP). In contrast, among whites, there was no association between race consciousness and BP. Similar experiences have been described for homosexuals in regard to homophobia.

Race-Based Medical Decision Making

Racism, sexism, and homophobia can interfere with the establishment of trust and delivery of effective medical care if providers create or establish barriers on the basis of their own internal biases, prejudices, and negative reactions to racial or cultural characteristics, such as skin color or clothing styles. In an early study, when primary care physicians viewed scripted video interviews with hypothetical patients with chest pain who had similar symptoms, risk factors, vital signs, and thallium stress test and electrocardiographic findings, they were less likely to refer African American women for cardiac catheterization than men and whites, even though the scripts varied only by race and gender. Similar disparities in treatment based on race and gender have been reaffirmed by early studies assessing the treatment of acute coronary syndrome. Furthermore, disparities in profiling can result in underdiagnosis and overdiagnosis and thus contribute to medical error.

Failure of Trust

Patients from minority communities have reason to be skeptical about the validity of medical research and appropriateness of medical recommendations. Participants in the Tuskegee study, for example, were not notified when effective treatment of syphilis became available because researchers wished to investigate the natural course of the disease. African American patients often rate their physician interactions as longer, more participatory, and having more positive effects when their physician is of the same race. However, this option for physician-patient congruence is rarely available to minority patients because only 4% of physicians are black, whereas 12% of the population is black. In the Agency for Healthcare Research and Quality (AHRQ) National Healthcare Disparities Report, blacks and Hispanics were found to be more critical of the patient–provider relationship than whites. A higher percentage of adult blacks and Hispanics rated their health care at less than 6 on a scale of 1 to 10 in the year prior to the report and believed that they would have received better care if they were of a different race or ethnicity.

Language and Effective Medical Care

According to the 2013 US Census estimates, 60 million Americans (21%) speak a language other than English at home, and 25.1 million speak English less than very well. Patients with limited English proficiency are more likely to defer needed services, leave against medical advice, miss appointments, fail to adhere to treatment regimens, lack a regular provider, and report poorer health status. A large body of literature has shown the importance of trained medical interpreters. Studies have shown that errors of ad hoc interpreters were more likely to result in clinically significant medical errors, such as omitting drug allergies and giving inaccurate instructions on dosing and route of administration. Furthermore the use of untrained nonprofessional employees as interpreters resulted in serious translation errors, including omissions, additions, and substitutions for what the patient is trying to say, and the use of relatives, particularly children, may violate privacy and disrupt family norms of authority.

Use of interpreters during clinical encounters can affect patient satisfaction. Satisfaction ratings for patients using ad hoc
interpreters are lower, and rates are lowest when an interpreter should have been used but was unavailable. In one retrospective study of Spanish-, Haitian Creole-, and Portuguese Creole-speaking patients presenting to the ED with chest pain, headache, and abdominal pain, the investigators found that the use of trained interpreters was associated with increased intensity of ED services, reduced ED return rate, increased clinic use, and lower charges during the next 30 days, without any simultaneous increase in length of stay or cost of visit.59

CULTURALLY COMPETENT APPROACH TO LANGUAGE BARRIERS

A new standard of care has been established that requires institutions and practitioners to provide for medical needs in a patient’s primary language and in a manner compatible with the patient’s health beliefs and practices.60 Health care institutions and providers are asked to collect data stratified by race, ethnicity, and language and to institute quality improvement efforts when cross-cultural differences in outcomes of care, process indicators, or patient satisfaction are detected. They are asked to develop culturally competent systems of care based on an assessment of the organization’s mission, goals, policies, practices and services, staff training needs, and current diversity of the staff.

After the assessment process, health care organizations must identify opportunities to improve the cultural competence of the organization and its delivery of health care services to a diverse population. At the top of the list is the improvement of interpreter services. Hospitals are asked to establish minimum performance standards for interpreters, which includes training in the culturally specific medical language and code of ethics. These requirements have been codified as a set of standards for culturally and linguistically appropriate services (CLAS) by the Office of Minority Health and AHRQ and published in the Federal Register.61

The medical interview is the heart of the medical encounter between physician and patient yet, in an interpreted interaction, neither patient nor physician is in a position to judge the accuracy or completeness of a lay interpreter’s translation. Clearly, omissions, additions, opinions, guesses, and distortions can lead to serious mistakes and unnecessary diagnostic procedures.

In a 2012 study, Flores and associates reported multiple mistakes made by professional interpreters in an analysis of audio recordings at two pediatric EDs. Mistakes included “addition, substitution and omission of words, use of phrases, idioms and language that did not exist in the patient’s language.” They reported that 18% of those involved potential clinical risks. Mistakes were found to be less frequent in professional interpreters with a minimum of 100 hours of training.41

Standards and certification for medical interpreters are needed to ensure consistency and quality. The Joint Commission (TJC) requires hospitals to provide professional interpretation services to every patient who needs it.62 The Massachusetts Medical Interpreter Association recommends that standards cover interpretation, cultural interface, and ethical behavior. Because the meaning inherent in the message is rooted in culturally specific beliefs, values, assumptions, customs, and norms, and language is itself an expression of culture, it may be necessary for a medical interpreter to go beyond a literal interpretation to explain unstated assumptions and find new ways of communicating untranslatable words or concepts. In addition to maintaining confidentiality, the medical interpreter has an ethical burden to uphold the trust of both parties and to assure them that the considerable power associated with the interpreter’s role will not be abused, and that information will be faithfully conveyed without interjection of the subjective opinions and thoughts of the interpreter. Even with such qualified interpreters, the emergency clinician still needs to monitor the flow of the interview and, from time to time, clarify meaning and ensure understanding. This can be done by having the interpreter repeat what he or she thought the patient meant and asking the patient to repeat what the interpreter said. It is important to observe the interaction for phrase length as an indication of material not translated or added by the translator.

Finally, failure to meet language and communication standards in clinical scenarios can lead to medical liability.63 In a study of medical malpractice claims of a malpractice carrier that insures providers in four US states, researchers found that 2.5% of the carrier’s total claims reviewed were related to language barriers, resulting in patient death or irreparable harm. The study reported that the carrier paid $2,289,000 in damages or settlements and $2,793,800 in legal fees between 2005 and 2009. In 32 of the 35 cases, the health care providers did not use competent interpreters. The following are examples of lack of provision of appropriate language services:

- Use of family members, friends, or children
- Failure to translate documents such as consent forms and discharge instructions
- Lack of documentation of a patient’s need for an interpreter or English language limitations
- Lack of documentation of the use of an interpreter and background and qualifications of the interpreter

MULTICULTURALISM, CULTURE COMPETENCE, AND HEALTH DISPARITIES: PROGRESS TO DATE

The 2003 IOM report revealed disparities in health care in the United States based along lines of race and ethnicity. The recommendations to reduce these health care disparities included “integration of cross-cultural education into the training of all current and future health professionals.” Progress has been slow in actually reducing health disparities,50 and gaps in economic resources between white and minority populations have actually widened,51 increasing the barriers impeding access to timely and effective care.

Forward movement has primarily occurred in the form of the establishment of guidelines and standards at local, state, federal, public, and private levels. TJC’s A Roadmap for Hospitals encourages hospitals to incorporate concepts from cultural competence, patient-centered care, and communication into their organizations.9 These efforts include increasing awareness of health disparities, efforts to improve collection of race and ethnicity data across systems of care, quality improvement, community outreach, increasing workforce diversity, patient education, provider education, and increased availability of interpretation services. A policy system of checks and balancing now exists, with national performance monitoring affecting accreditation of health care organizations.

In 2011, patient-centered communication standards were included in TJC’s Comprehensive Accreditation Manual for Hospitals.54 After a period of monitoring hospitals for compliance of standards without any effect on accreditation, compliance has progressed as an expectation and is taken into account in the accreditation process.55

In another example of guideline development, the National Committee for Quality Assurance developed and released rigorous standards for monitoring and evaluating multicultural health care in 2010. Multicultural health care distinction is conferred on health care organizations that conform to acceptable practices regarding considerations of race and ethnicity in language data collection, access and availability of language services, practitioner network cultural responsiveness, programs for culturally and linguistically appropriate services, and overall efforts to reduce health care disparities. In a similar effort, the National Quality Forum released a report in 2011 on quality measures to assess cultural competence. In education, the Liaison Committee on
Medical School Education now includes cultural competency in its accreditation standards. Medical students should learn to recognize and appropriately address gender and cultural biases in themselves and others and in the process of health care delivery.

Disparities awareness has also been included in health care reform. The Patient Protection and Affordable Care Act (Health Care Reform Act) signed into law in March 2010 requires data collection on race, ethnicity, primary language, disability status, and gender. These data can identify areas of concern and provide opportunities for intervention. This law follows recommendations from the 2003 IOM report and raises awareness of culture and disparities. In addition to national activities, many states have taken action. For example, the New Jersey State Board of Medical Examiners requires that physicians licensed in New Jersey complete six credits in cultural competency (Rule NJAC 13:35-6.25).

Using Cultural Competence to Cross the Barrier of Different Beliefs, Values, and Life Experiences

Physicians and patients have a culture that they bring into the examining room. Differences between their cultures have an impact on the physician-patient encounter. Awareness of one’s own values and those of others can enhance satisfaction and health outcomes. The Society for Academic Emergency Medicine task force report cautioned, however, that it is dangerous to hold strong preexisting assumptions about any cultural group because variations within cultures often exceed variations between them. A patient who is thoroughly acculturated into US society may be offended by a health care provider’s attribution of traditional beliefs. Even in the context of a busy ED encounter, it is necessary and feasible to get to know the individual patient sufficiently to make a rough assessment about her or his level of acculturation or, at least to ask rather than assume.

In some cultures, the diagnosis of specific diseases can be particularly problematic. For example, in African American and Puerto Rican communities, cancer is often perceived as a fatal disease. Patients may therefore avoid initial evaluation or choose no treatment when they are diagnosed, even when the cancer is identified at an early stage and the prognosis is good. A health care provider who understands these health beliefs and concerns can work collaboratively with patients to provide health information in a format that the patient can accept.

Alternative healing systems have strong cultural roots. In 1997, the US population made an estimated 629 million visits to providers of alternative health care—approximately 243 million more visits than to conventional health care providers and an increase of 47% since 1990. The National Center for Complementary and Integrated Health maintains an extensive database of literature on alternative healing methodologies in the United States.60-69

Folk medicine is too diverse for providers to know all possible practices, but emergency clinicians need to be aware of the more common folk therapies. For example, more than a few physicians have called social workers to investigate children with apparent bruises caused by coining, which involves vigorous rubbing of the skin with coins and warm oil (tiger balm) to release the “bad wind” (reduce fever). These parents, who have attempted to help their children by using health care practices that are widely accepted in their communities of origin, feel accused, and the trust between the physician and family may be irrevocably lost. Similarly, herbal remedies can be effective or at least harmless, but they can occasionally be toxic, as in the case of clay ingestion by pregnant women, marijuana tea to treat asthma, and powders containing high concentrations of lead oxide to treat empaacho, a condition in which it is believed that a substance (usually food or saliva) gets stuck to the walls of the stomach or intestines, causing an obstruction. Specific uses of folk medicine need to be elicited respectfully in a careful history and evaluated. Recommendations can then be presented nonjudgmentally, and alternative folk remedies that are benign can be prescribed along with needed allopathic medications.

The practitioner and patient will inevitably bring different beliefs and values to the medical encounter; the key to cultural competence is respectful negotiation of these differences without imposing the power of the physician’s expertise, thus protecting the patient’s autonomy. If patients are satisfied, they will carry out follow-up recommendations and return to the ED in the future when they need emergency care.

Interpreting the Culture of Medicine to Patients From Diverse Backgrounds

There are inherent conflicts between the culture of medical care and the cultures of many patients. Physicians are expert in diagnosis and treatment of diseases, which represent abnormal structures or functions of the human body (the pathophysiology of disease states). On the other hand, patients experience illness, a subjective feeling state that is interpreted through the lens of culture and has a personal and social meaning. The patient is an expert on his or her own illness and its effects on daily living, whereas a physician is expert on the effects of diseases on organ systems. Both ways of looking at the world have validity, but they are radically different. Unfortunately, the culture of medicine tends to recognize only its own interpretation and perspective. A culturally competent approach recognizes both and works to integrate the best of both worlds.

A patient may have very high blood pressure, HIV infection, or early cervical cancer and not experience symptoms. If patients do not feel sick and experience no alteration in functioning, they may not accept a physician’s diagnosis. On the other hand, a patient may feel sick—be ill, weak, and dizzy, with extreme fatigue or abdominal pain—yet the physician is unable to diagnose a disease, despite a thorough history, physical examination, testing, and appropriate consultation. For example, susto, an illness recognized by Mexican Americans, causes listlessness, insomnia, depression, and anorexia and is believed to be caused by exposure to a frightening experience. Treatment requires the patient to speak openly about the events that led to the susto, followed by bed rest and a ritual that includes prayers, incantations, and barridas—sweeping of the body with an egg, candle, or herbal tea.60

To be most effective, physicians need to investigate how patients view the causality of their illnesses and how they experience them to negotiate a therapeutic intervention. Exploration might take the form of comments and questions, such as, “Help me see through your eyes how you understand this problem. Have you or someone you know experienced it before?” The role of the physician is to accept the patient’s experience as uniquely his or hers or, when possible, to reframe it in terms of medical knowledge. Then both physician and patient will be satisfied with the outcome of the encounter.

Care and Communication for Victims of Community Violence

For several years, the CDC has proclaimed that “youth violence is a public health issue for individuals and communities.” Annually, more than 5,000 young people between the ages of 15 and 24 years succumb to death by homicide, making homicide the second leading cause of death for this age group.61 In 2011, more than 707,000 youths between the ages of 10 and 24 years were treated in US EDs for violent injuries.62 Because urban black youth and other minorities are overrepresented among victims of violence in urban settings, racial and ethnic stereotyping can play a direct
role in trauma care. Assumptions of responsibility and guilt by emergency clinicians can produce a hostile environment for patients who have been shot or stabbed. Language that assumes blame (“What did you do?” instead of “What happened to you?” or “I’m sorry this happened to you”) indicates a lack of understanding of the complexity of trauma, its neighborhood context, and the psychological impact of adverse childhood events, which are often at the epicenter of the cycle of violence.\textsuperscript{62-65} Trauma can cause neurobiologic and psychosocial effects such as hyperarousability, hypervigilance, aggressive responses to fear and threat to safety, loss of empathy for others, withdrawal, anxiety and depression.\textsuperscript{66-68} The emotional response to trauma of a victim of violent injury can be misinterpreted as negative behavior. A victim might be seen as ill-willed versus in need of care and healing. Providers and health care staff witnessing the responses of these violently injured youth have an opportunity to mitigate the trauma or inadvertently enhance it through retraumatization.

Trauma-Informed Care

A new construct, trauma-informed care,\textsuperscript{69,71} is an alternative perspective that can enhance opportunities for productive encounters, self-reflection, and positive medical outcomes during a vulnerable time for an injured young person. The basic set of principles includes the creation of a safe physical and emotional environment that is sensitive to the needs of victims of violence, promotes recovery, and prevents revictimization. Symptoms are seen not as pathologic changes but primarily as attempts to cope and survive. Trauma-informed care can result in an injured youth’s choosing “change” versus unsafe behavior that could result in injury, re-injury, or incarceration. Health care providers can contribute to positive outcomes and life choices of victims of violence. Understanding and maintaining an awareness of the comprehensive effects of trauma can help comprehend posttraumatic behavior and minimize revictimization. From providers, this respect, compassion, and familiarity with the manifestations of trauma.

One of the policies of the 2011 ACEP Revised Code of Ethics states that emergency clinicians have a “duty to promote the public health.” The code states that “Emergency physicians have first-hand knowledge of the grave harms caused by firearms, motor vehicles, alcohol, and other causes of preventable illness and injury” and suggests that emergency clinicians have a responsibility to act: “Inspired by this knowledge, emergency physicians should participate in efforts to educate others.” EDs and inpatient trauma services present a unique opportunity for interventions to reduce youth violence and support communities. Several cities have established effective peer-model, hospital-based, violence intervention programs that use interventions geared specifically toward reducing recidivism among vulnerable and violently injured youth.\textsuperscript{69,70} These programs can save hospitals and the criminal justice system millions of dollars through reducing retaliation and recidivism and, most importantly, saving lives.\textsuperscript{22-26}

Role Expectations in Western Medicine: Opportunities for Misunderstanding

The culture of medicine, especially in EM, may have its own set of patient expectations, rules and regulations, language, and dress distinctions that reflect a hierarchy of authority, characterization of patients as good or bad, and different sets of behaviors toward patients, depending on the category to which they have been assigned. People from different cultures may find it impossible not to violate some of the unwritten negative and stereotypical rules and regulations of the ED. Every medical encounter is potentially a cross-cultural experience, and negotiation of the divide is a challenge for patients and providers. Cultural competence involves reframing many of these unstated rules because they prevent us from looking beneath the surface and addressing real problems. When a patient comes in with vague complaints, there may be a social stressor that has tipped the balance of mental health. There may be circumstances that the patient does not feel comfortable sharing with the provider because of cultural, racial, sexual orientation, or language barriers, or there may have been an overload of negative stimuli related to racial and ethnic discrimination—a crisis for the person and the body this person inhabits.\textsuperscript{72-74} People from minority cultures experience stressful events daily that white providers, secure in their socioeconomic status and membership in the dominant majority, can only imagine. There is mounting evidence that these types of negative encounters engender clinical depression and anxiety and contribute to hypertension and other medical sequelae.

Studies have shown disparate patterns of ED use based on race and ethnicity. Nonwhite patients have been found to use the ED more as a source of care.\textsuperscript{75,76} Patients who overuse or abuse the ED are seen as so-called bad patients, but the reasons patients give for using the ED are entirely rational. The ED does not require an appointment to receive care, provides sophisticated medical technology, operates 24 hours a day, provides services that are often covered by health insurance plans (whereas other options often are not), has a tradition of free care, and is often located close to inner city neighborhoods.

To practice good medicine in this health care and social environment, emergency clinicians should critically question and reframe the moralistic good patient–bad patient paradigm. We, like our patients, are at the whim of forces beyond our control, and patients and practitioners will experience higher levels of satisfaction if these issues are addressed directly. Patients must take responsibility for their own behaviors whenever possible, but physicians can and should work with health care institutions to adopt policies that improve access to culturally competent health care. These actions can help create a safe environment for practitioners and patients.

CULTURAL COMPETENCE AND PATIENT-CENTERED CARE: NEW MODELS

Models for cultural competence and patient-centered care have evolved separately yet in tandem. The goal of both is to improve the quality of the health care experience in a multicultural world, and there are areas of overlap.\textsuperscript{81-85} Cultural competence evolved from the perspective of recognizing and respecting individual difference and the impact of individual interpretation on health, illness, and health care delivery. Patient centeredness addresses systems of health care delivery, improving access, and meeting patients where they are to maximize opportunities for successful health care.\textsuperscript{83} Ideal health care systems should be designed to incorporate principles of cultural competence and patient centeredness. A health care system built on patient-centered principles represents the heart of cultural competence—seeing the problem and solution from the point of view of the patient.\textsuperscript{85} Studies have suggested that patient-centered care might also be associated with improved clinical outcomes and patient satisfaction at reduced cost.\textsuperscript{85}

EDUCATION

Education about the impact of culture on health care encounters is a key component for the development of culturally appropriate health care and is a requirement for organizational accreditation. Students and residents in training consistently express greater levels of comfort in multicultural environments when they have had preparatory training. Training also helps students and residents understand that their own culture also affects clinical
encounters and is equally participatory. Continued re-education raises awareness and imprints consciousness more permanently, establishing a conceptual norm for those interacting and working in multicultural environments. Linkage of cultural competence with ethical constructs of equal distribution of resources and social constructs of justice gives meaning to principles and context beyond the memorization of appropriate responses to model situations.

Medical schools are now required to include cultural competency training in their curriculum for accreditation. Faculty and students should demonstrate an understanding of the manner in which people of diverse cultures and belief systems perceive health and illness and respond to various symptoms, diseases, and treatments. Medical students should learn to recognize and appropriately address gender and cultural biases in themselves and others and in the process of health care delivery.86,87

Members of lesbian, gay, bisexual, transgender, questioning (LGBTQ) communities are among the many patients seeking emergency care.88 Implicit and explicit bias against LGBTQ people exists in society and, by extension, in health care.89-91 Medical literature suggests a need for enhanced education for trainees and providers to have knowledge and insight for the provision of optimal and appropriate care for this population.92 Challenges and barriers to health care for LGBTQ are not widely known. LGBTQ patients identify lack of provider education as a barrier to care. Many LGBTQ patients avoid accessing the health care system, citing barriers such as discriminatory behavior and poor treatment from providers and other health care staff. Experiencing negative encounters causes patients to avoid seeking medical treatment, including emergency care. Social marginalization and inequality is associated with health disparities. Among the LGBTQ population there are disproportionate levels of substance abuse, tobacco use, psychiatric disorders, suicide, youth homelessness, obesity, and disease. Lesbian, bisexual, and transgendered women engage in less routine care and screenings than other women.89-93

Education and training in LGBTQ patient treatment and health is underdeveloped. A 2014 survey of EM residency programs found that only 26% included a specific LGBTQ lecture, and only 33% incorporated topics on LGBTQ health into their curriculum.94 These findings suggest a paucity of education of EM residents on LGBTQ health needs. LGBTQ health education is not included in the most recent model of clinical practice in EM.95 The need for cultural competency and provider education on LGBTQ health has been stated by the IOM, TJC, and Department of Health and Human Services.96-98

Making consistent upgrades in medical education is the best opportunity to cause a permanent shift in the paradigm of multicultural patient-physician clinical interactions in the future.

**RECOMMENDATIONS**

Diversity among the ED patient population poses a challenge to emergency clinicians. Recognition of cultural differences, knowledge about diverse cultures, awareness of the health impact of cultural beliefs and practices, and sensitivity to patients’ needs can reduce access barriers and improve clinical outcomes and hospital-community relationships while reducing the number of repeated visits and costs of health care. Diversity education also creates a rich environment for conceptualizing and researching health problems.

There are many opportunities for EDs and their institutions to improve their care of multicultural communities. These include plans to address problems related to the following:

- Lack of protocols for patient care
- Lack of resources for translation and cross-cultural interpretation
- Incorrect perception that attention to cultural competence adversely affects flow and efficiency
- Lack of cross-cultural teaching guidelines and standards in medical education
- Inadequate recruitment and retention of minority residents, faculty, and practitioners
- Lack of pathways for communication and collaborative work with communities

Concrete recommendations, based on the additional legal, regulatory, and policy measures were highlighted in an *Academic Emergency Medicine* editorial and include the following:

- Patients in public managed care organizations should have the same patient bill of rights as patients in private health maintenance organizations.
- The number of health care providers who are members of racial and ethnic minority groups should be increased.
- Resources should be adequate to enforce penalties for civil rights violations.
- Incentives to promote disparities should be stringently limited.
- Health care professionals should have opportunities for cross-cultural education.
- Patient participation in decision making should be enhanced through education.
- Community health care workers and advocates should assist patients to negotiate the health care system successfully.
- The diversity of faculty and residents must be improved.
- A cross-cultural curriculum should be developed for residency training and continuing education.
- Physicians should educate themselves and the general public about the need to eliminate racial and ethnic disparities in health care.

**SUMMARY**

Changing demographic landscapes in EDs have set the stage for multicultural appropriate care. The process of change for the development of culturally competent medical systems has been slow, but progress is occurring. Evolution of culturally appropriate environments for patients and their families has begun on all levels and, with the development of new standards and performance-monitoring systems, assurance of established culturally competent systems will be an expectation. These expectations are important and tightly linked to safety and quality. The linkage of cultural competence to social justice broadens the depth of comprehension for the learner and provides opportunities for enhanced engagement with consumers and greater quality of care.

There is greater awareness of and movement toward a health care system that is rooted in cultural competence and patient centeredness. It is imperative that EDs invest in the development of their health care systems and educate all staff. ED patients are often unknown to providers, who have one window of opportunity to obtain accurate information and make a correct decision. Decisions are heavily based on one's ability to listen and learn what matters to patients and successfully engage with patients and
their families, engendering comfort, trust, and respect. Treatment plans that are created with patients and are based in what matters to them have the greatest opportunity for success. Continued education at all levels is key and should include everyone working in health care, especially those who engage with consumers. Multiculturalism education should be integrated into medical school curricula, physician training programs, allied health programs, new employee orientation, and staff in-service programs on a regular basis.

The process of creating a successful plan to move cultural competency from a theoretic model to one of action and implementation has been outlined in six principles that incorporate key points recommended by the IOM report of 2003 for systems aligned with new cultural competence standards and expectations:

- Community representation and feedback at all stages of implementation
- Cultural competency integrated into all systems of the health care organization, particularly quality improvement efforts
- Ensuring that changes made are manageable, measurable, and sustainable
- Making the business case for implementation of cultural competency policies
- Commitment from leadership
- Staff training on an ongoing basis

Essential cultural competence tools for providers include recognition of cultural differences, respect for individual opinions and perspectives about health and illness and, most importantly, ability and willingness to negotiate differences to offer the best opportunity for good health care outcomes. Culturally appropriate health care systems should be incorporated into EDs, which serve as the gateway to our health care institutions.

**KEY CONCEPTS**

- Changing demography and an evolving culture in the United States is changing emergency medicine practice.
- Disparities in health and health care delivery continue, despite efforts to improve care. Emergency clinicians and their institutions will need to be part of the solution—treating preventable conditions that become crises because of reduced access to primary care and specialists and acting as advocates for strategic system change to eliminate disparities in their institutions.
- Emergency departments (EDs) will contribute to breaking cycles of illness if they seize opportunities to establish treatment plans and interventions that focus on social determinants of health, health literacy, and empowerment of patients to participate in their care.
- Treatment plans that are created with patients and are based in what matters to them have the greatest opportunity for success.
- Emergency clinicians will improve the quality of care provided if they can meet federal standards for culturally and linguistically appropriate care, recognizing that patients with limited English proficiency have a right to medical interpretation.
- Culturally sensitive, patient-centered, and trauma-informed care will improve patient—emergency clinician communication and satisfaction, decrease medical errors, and promote patient follow-through with recommendations.

Which of the following factors has not been identified as a health care disparity for minorities?

A. Lack of prenatal care
B. Relatively low number of minority providers
C. Do contact and empathy mitigate bias against gay and lesbian people among heterosexual first-year medical students?
D. Violence is preventable: a best practices guide for launching and sustaining a hospital-based program to break the cycle of violence.

Answer: C
e7.2. Patients’ cultural perceptions can have significant impact on how they perceive their provider and the care they are receiving. Which of the following methods can be used by providers to approach different cultural perceptions so as to enhance the provider-patient relationship?
A. Being aware of one’s own cultural values
B. Developing assumptions of cultural perceptions based on patients’ ethnicity or race
C. Limiting participation of alternative therapies and folk medicine in the patient’s care plan
D. Maintaining the role of the physician as the decision maker, even when it may conflict with the patient’s autonomy

Answer: A

e7.3. A helpful language translator can be essential in communication with a patient who is facing a language barrier. Which of the below methods are recommended for using an interpreter during a medical examination?
A. Asking the patient to have friends or family translate discharge instructions for them
B. Maintaining easy access to trained medical interpreters
C. Only obtaining an interpreter if the patient requests it
D. Using a family member is appropriate as long as they are older than 18 years
E. Using health care staff members who are fluent in the patient’s language

Answer: E

e7.4. Which of the following is not a benefit of using trauma-informed care when interacting with victims of violence?
A. Decreased need for pain medications
B. Decreased risk of injury or re-injury
C. Decreased risk of long-term psychologic sequelae related to patient’s injury
D. Improved patient understanding of posttraumatic behavior

Answer: A

e7.5. Which of the following recommendations was not made by the Institute of Medicine to aid in decreasing disparities in health care?
A. To create a different patient bill of rights for those in public versus private managed care organizations
B. To create more opportunities for cross-cultural education for health care providers
C. To have physicians educate the public regarding the necessity of eliminating racial and ethnic disparities in health care
D. To increase the number of community health care workers and advocates who can assist patients in navigating the health care system
E. To increase the number of health care providers from racial or minority groups

Answer: A
CHAPTER e8

The Geriatric Emergency Department*

Michael E. Stern

PRINCIPLES

Follow-Up and Transition of Care

Quality Improvement

KEY CONCEPTS

- Physical and process characteristics of the current ED model can present a challenging environment for managing older patients and undermines the ability of the modern ED to serve as their care transition hub.
- Older patients are more likely to present with complex medical problems, receive a greater number of diagnostic tests and treatment regimens, have longer lengths of stay in the ED, require special needs during their visit, and be admitted more often.
- The new consensus-based GED guidelines were published to provide a standardized set of guidelines that can effectively improve the care of the geriatric population in the ED.
- The guidelines consist of 40 specific recommendations in 6 general categories: (1) staffing and administration; (2) equipment and supplies; (3) education; (4) policies, procedures, and protocols; (5) follow-up and transitions of care; and (6) quality improvement measures.
- The GED guidelines represent recommendations and are not intended as a mandate for every ED.

The Geriatric Emergency Department

Michael E. Stern

PRINCIPLES

Background

The most significant demographic shift in the United States in the early twenty-first century is the rapid increase in the growth of the population aged 65 years and older. As a result of the baby boomers coming of age in 2011, this trend will continue for several decades. In addition, as a result of advances in health education, pharmacotherapy, and health-related technology, 20% of the US population, nearly 75 million people, will be aged 65 years and older in 2030, a dramatic increase from the current 13%. Of particular significance, the most rapidly growing segment of the population is the oldest old, aged 85 years and older, who will represent nearly 25% of Medicare beneficiaries by 2050.

The US health care system has begun to recognize the complex challenges that exist in caring for this so-called silver tsunami. Federal, state, and community-based programs and initiatives have been put in place to improve the health and care of older adults. Changes in federal and state regulations and insurance reimbursement—the passage of the Affordable Care Act and new guidelines from the Centers for Medicare & Medicaid Services (CMS)—have begun to change the landscape of care provided to older patients by hospitals and individual providers. However, fewer physicians are choosing primary care and specialty training in geriatrics, despite older adults requiring more services.

Older Patients in the Emergency Department

The emergency department (ED) is increasingly shouldering the burden of the care of older adults. From 1993 to 2003, ED utilization rates by older adults increased from 12% to 16% of all ED visits, and there was a 34% increase in the visit rate/100,000 population of patients aged 65 years and older throughout the study period. As early as 2002, ED use was higher for older patients than for younger adults, with approximately 58% of 75-year-olds visiting the ED, as compared to 39% of those of all ages, and ED use increased with increasing age. In the Institute of Medicine’s 2006 report, care for older adults was found to be increasingly sought in EDs. In the 2013 Rand Report, which evaluated the evolving role of hospital EDs in the US health care system, it was found that EDs are being increasingly used for complex evaluations, emergency clinicians are the principal decision makers for half of all hospital admissions, and hospital admissions of Medicare patients are growing faster than any other group, with 6 of 10 patients being admitted through the ED.

Older patients are more likely to present with complex medical problems, receive a greater number of diagnostic tests and treatment regimens, have longer lengths of stay in the ED, require special needs during their visit, and be admitted more often. An ED presentation for any reason has been found to be a sentinel event for older adults, conferring an increased risk of functional decline, medical complications, and poorer health-related quality of life, as compared to before their visit. In one study, an ED return visit, hospitalization, or death within 3 months occurred in up to 27% of older adults after discharge to home from an initial ED visit.

The current model of care delivery in the ED is designed for rapid evaluation, treatment, and turnover of acutely ill and injured patients. The physical space and layout are designed for maximal use of resources and improved throughput at the expense of privacy and a quiet environment (eg, hallway beds, lack of space for family or caregivers). Choices in equipment and materials favor cost savings, space conservation, and ease of cleanup (eg, bright fluorescent lighting, thin, narrow mattresses, slippery vinyl flooring) over the special care needs of older adults. In addition, the care transition for older adults deemed safe to discharge from the ED is fraught with problems, including inadequate process for discharge instructions, suboptimal communication with primary care providers, and delayed or absent follow-up appointments. These physical and process characteristics of the current ED model can present a challenging environment for managing older patients and undermines the ability of the modern ED to serve as their care transition hub.

The paradigm of the busy contemporary ED is ill-suited for typical geriatric patients, who have atypical presentations of disease and trauma, often vague complaints, polypharmacy, age-specific multifactorial syndromes (eg, falls and delirium), complicated comorbid disease burdens, and functional and cognitive impairments. Also, a general lack of geriatric specific training across all levels of providers and a dearth of focused geriatric emergency medicine research have contributed to limited evidence-based clinical protocols for older emergency medicine patients. As a result, care delivery in the current ED environment for this growing vulnerable population has been, in many settings, suboptimal.

GERIATRIC EMERGENCY DEPARTMENT GUIDELINES

In recognition of the pressing need for specialized care for older adults in response to this rapidly growing demographic, the first of several geriatric emergency departments (GEDs) opened in 2008 and 2009. These GEDs seek to provide care tailored to the special needs of geriatric patients in a setting that is conducive to appropriately care of older patients. Since then, competition among hospitals across the country has risen to attract older patients to use specific EDs for their care.

A surge in self-designated GEDs has taken place in the last few years, with over 90 hospitals nationwide now claiming to have GEDs. This has raised the salient question of exactly what sort of geriatric patient care is actually being delivered in these EDs, because very few of them are located in academic centers, and there are little data supporting their efficacy. In 2013, the first research study that systematically identified and qualitatively characterized the existence, locations, and features of GEDs across the United States was conducted and found significant variation in the capacities and components of a GED, indicating a need to address future standards for them.

In an effort to provide a standardized set of guidelines that can effectively improve the care of the geriatric population in
the ED, new, consensus-based GED guidelines were published in early 2014. Representatives from the American College of Emergency Physicians (ACEP), Society of Academic Emergency Medicine (SAEM), American Geriatrics Society (AGS), and Emergency Nurses Association (ENA) collaboratively developed guidelines over a 2-year period, including academic and community providers. These guidelines are based on an 80% consensus among the representatives and were validated using existing literature.7

The GED guidelines were created to promote improved ED care for older adults while addressing the unique needs of this population. The guidelines consist of 40 specific recommendations in six general categories: (1) staffing and administration; (2) equipment and supplies; (3) education; (4) policies, procedures, and protocols; (5) follow-up and transitions of care; and (6) quality improvement measures. This template outlines how to construct an effective GED program. It is important to note that the GED guidelines represent recommendations and are not intended as a mandate for every ED. Instead, the document provides the potential steps to be taken, rationale for these recommendations, and outline of the resources available to aid in their implementation in any ED. These recommendations target a coordinated care approach and focused resources on the most common needs of the typical geriatric ED patient. To create a GED, the specific GED guideline recommendations are categorically described.7

**Staffing and Administration**

The staffing and administration of the GED should be comprised of a multidisciplinary team of care providers who have specific geriatric training and education to focus on high-quality geriatric care. The GED guidelines recommend protocols to set qualifications and establish responsibilities for the GED medical director, GED nurse manager, staff physicians and nurses, medical staff specialists (including a geriatric consultation service) and provide accessibility to ancillary services (eg, social workers, geriatric case managers, pharmacists, physical and occupational therapists). The goal is the establishment of targeted ED and in-hospital staff and their coordination with local outpatient resources to improve ED, inpatient, and follow-up care for older adults.

**Equipment and Supplies**

Improved geriatric care requires a keen understanding of the specific needs and vulnerabilities of this unique patient population. Incorporating key concepts from the domain of environmental geriatrics, the development of a GED should adapt the physical space with structural modifications and introduce and implement equipment and supplies designed for the safe, comfortable, and effective evaluation and management of geriatric patients while decreasing iatrogenic complications. Enhancements that address issues of mobility, comfort, safety, and behavioral needs (including memory cues and sensory perception of vision and hearing) are desirable.

Suggested furniture improvements include reclining examination chairs that facilitate safe transferring, extra thick and soft gurney mattresses (or, even better, pressure-distributing foam mattresses) designed to decrease the possible development of pressure ulcers, and upholstery choices that are soft, moisture-proof, and easy to clean, designed to protect the fragile skin of older patients and reduce contamination by hospital-associated pathogens. Special equipment to equip a GED includes warm blankets, no-slip fall mats, bedside commodes, walking aids and devices, hearing aids, monitoring equipment, and condom catheters to reduce the risk of catheter-associated urinary tract infections (CAUTIs).

Visual orientation improvements include soft lighting, with a combination of ambient and spot lighting, designed to increase overall lighting and reduce glare. Patients should have control of the lighting in their respective rooms. Exposure to natural light is most desired because it has been shown to improve recovery times and decrease delirium.9

Color and pattern choices for facilities and structures should be made with an understanding of the vision and perception changes that accompany aging. Warm, light-colored walls (yellows and oranges) with a matte finish are preferable. Blues and greens are difficult to differentiate for many older patients. Avoid monochromatic color schemes and allow for colors to contrast between horizontal and vertical surfaces. Sharp, dominant contrast patterns may be disorienting and hinder movement.

Acoustic orientation improvements should provide better communication and decreased levels of anxiety and delirium. Private rooms and the use of sound-absorbing materials (eg, curtains, ceiling tiles) are preferred to reduce background noise and increase patient privacy. Portable hearing assist devices are helpful. Reduction in overhead paging and machine noise should be a targeted goal. A choice of music has been shown to reduce anxiety, heart rate, and blood pressure.10,11 Enhanced signage is also helpful to improve communication.

Some miscellaneous safety enhancements include elimination of floor thresholds that separate spaces (eg, between a hallway and bathroom) because any elevation is a major falls risk. Doors should have handles and not round knobs for ease of use. With minimal expense, the aforementioned equipment and supplies suggestions can help improve geriatric care. Although a dedicate, separate geriatric ED may be the ultimate goal, most hospitals can effectively implement a program to develop a GED by converting the existing space and beds into a geriatric-friendly environment with the equipment and supplies described.

**Education**

The education of a multidisciplinary staff regarding the specific needs of this unique population is a key component to the implementation and success of a GED program. Residency program curricula, ED staff training, and continuing medical education should incorporate the established geriatric emergency medicine core competencies12 and provide specialty-specific training, focusing on contemporary, research-based, geriatric-specific material, with regular assessment for interdisciplinary core competencies. A number of instructional platforms can be used, including didactic lectures, Internet-based materials, case simulations, case-based conferences, journal clubs, and bedside clinical teaching. The GED educational program should be geared toward increasing and maintaining staff awareness and knowledge of the geriatric population’s needs and implementation of specific policy and procedure initiatives. These should include didactic educational sessions, in-service sessions about geriatric-specific equipment, implementation of bedside assessment tools, and community awareness, involvement, and outreach, including emergency medical services (EMS) personnel, community-based organizations, and patient and family educational self-management materials.

Although individual EDs should tailor their educational content needs to their respective institutions, GED guidelines recommend the inclusion of the content outlined in Box e8.1.

**Policies, Procedures, and Protocols**

Specific policies, procedures, and protocol initiatives are an integral part of the application of GEM educational content and systematization of evidence-based clinical care for older adults. They are designed to implement a directed comprehensive
Geriatric Education Guideline Content

Atypical presentations of disease
Trauma, including falls and hip fracture
Cognitive and behavioral disorders
Modifications of emergent interventions for older patients
Medication management
Transitions of care and referrals to services
Pain management and palliative care
Effects of comorbid conditions
Functional impairments and disorders
Management of diseases peculiar to the geriatric adult
Abdominal pain
Weakness and dizziness
Iatrogenic injuries
Cross-cultural issues involving older patients in the emergency setting
Elder abuse and neglect
Ethical issues, including advance directives

Follow-Up and Transition of Care

The new CMS directive to reduce hospital admissions notwithstanding, it has been known for some time that geriatric patients are particularly vulnerable to the deleterious consequences of hospitalization, including nosocomial infections, functional decline, increased rates of delirium, and iatrogenic complications. Reducing hospitalizations and providing safe discharge and outpatient follow-up, provision of palliative care, and patient death.

The policies, procedures, and protocols listed by the GED guidelines are recommended to be comprehensive and adaptable to the specific needs of a particular ED. When possible, they are evidence-based and intended to become part of the routine care of patients. Sample policies and procedures are included in the GED guidelines manuscript.

Quality Improvement

As part of a GED program, outlined by the GED guidelines, a quality improvement (QI) system should be implemented to collect and monitor pertinent and prevalent geriatric emergency care indicators, including incidence of injurious falls and documentation of falls risk assessment, catheter use and CAUTIs, medication reconciliation, pharmacy oversight of adverse drug-related events and ED use of high-risk medications, and restraint use. Also, it should routinely review geriatric ED volume, admission and readmission rates, intensive care unit (ICU) admissions, ED return visits within 72 hours, completion of follow-up reevaluation for discharge patients, transfers to other facilities, suspected abuse or neglect, and deaths.

The QI program should be established and monitored by the GED medical director and GED nurse manager to ensure increased staff education and program success. It should include an interface with prehospital care, ED, trauma, and critical care services, alternative care facilities, and hospital-wide QI activities.

Criticisms of the GED guidelines have already been voiced by some emergency medicine (EM) providers. Specific concerns include a fear of partitioning the ED, as has occurred with pediatrics, an increase in cost and decreased efficiency, the need to maintain general expertise among EM physicians, the lack of evidence-based data on which the recommendations were made, the fact that some guidelines were extrapolated from evidence originally studied in other clinical settings, and the belief that these changes will be too logistically difficult and take too much time.

Numerous factors have led to the advent of the GED, and the concept is likely here to stay. The goal to improve the evaluation and care of the increasing number of geriatric patients presenting to the ED is clearly exigent. Reliable tools, protocols, and guidelines must be developed, implemented, and studied to ensure diagnostic accuracy, decrease adverse events, and improve patient outcomes. Fortunately, the new GED consensus guidelines are a sound and flexible starting point. They do not need to be wholly embraced, instead lending themselves to modifications and institution-specific adoptions. The so-called protocolization and implementation of the guidelines may ultimately improve patient flow, operational efficiency and, most importantly, the quality of care delivered to older adults. Although the GED guidelines have yet to be studied, they will hopefully effect substantive change in many EDs, improve the emergency care of older adults, and provide the foundation for future education and research.

CHAPTER e8: QUESTIONS & ANSWERS

e8.1. What is the most rapidly growing segment of the US population according to age?

A. 5–10 years
B. 15–20 years
C. 55–60 years
D. 65–70 years
E. Older than 85 years

**Answer:** E. The most rapidly growing segment of the population is the “oldest old,” aged 85 years and older, who will represent nearly 25% of Medicare beneficiaries by 2050.

e8.2. The geriatric ED (GED) guidelines developed by ACEP, SAEM, AGS, and ENA make recommendations in which of the following areas?

A. All of these
B. Education and patient care protocols
C. Follow-up and transitions of care
D. Quality improvement measures
E. Staffing, supplies, and administration

**Answer:** A. The GED guidelines consist of 40 specific recommendations in six general categories: (1) staffing and administration; (2) equipment and supplies; (3) education; (4) policies, procedures, and protocols; (5) follow-up and transitions of care; and (6) quality-improvement measures.

e8.3. The geriatric ED guidelines recommend older adult–specific educational content in which of the following areas?

A. All of these
B. Atypical presentations of disease
C. Cognitive and behavioral disorders
D. Medication management
E. Pain management and palliative care

**Answer:** A. See Box e8.1.

Treating Symptoms Requiring Palliation at the End of Life

Hospice Care and the Emergency Department

KEY CONCEPTS

- Palliative care is a physical, spiritual, psychological, and social support provided to patients and families at any stage of serious illness.
- Palliative care teams are specialized interdisciplinary teams that should be involved early in the course of illness.
- Hospice care is a care system for patients and families with a prognosis of 6 months or less if the disease runs its usual course; referral from the emergency department (ED) may be indicated.
- Patients at the end of life generally follow one of four terminal illness trajectories: sudden death, organ failure, cancer, or frailty.
- Functional status is a strong predictor of decline and progression to death in patients with advanced illness.
- Goals of care conversations that outline patient and family hopes and expectations of interventions should be carried out.
- Emergency clinicians should make recommendations for care plans, interventions, and treatment courses based on prognosis, goals of care, and expected benefit to meet the identified goals of care.
- Key communication skills include breaking bad news, death disclosure, and assessment of goals of care.
- Interpretation of an existing advance care plan or receipt of aprehospital order (eg, POLST—Physician Orders for Life-Sustaining Therapy) should factor into ED treatment plans in the context of the patient’s illness trajectory.
- Advance care planning may occur in the ED in the form of goals of care assessment followed by recommendations and orders placed by the emergency clinician to implement the plan.
- Symptom management is critical at the end of life; common symptoms are dyspnea, pain, delirium and agitation, and secretion management.

The palliative care movement has developed as an expansion of end-of-life care to include not only hospice-eligible patients but also patients with incurable, debilitating, chronic noncancer illnesses (eg, chronic obstructive pulmonary disease [COPD], congestive heart failure) that require symptom control, often in addition to some disease-modifying interventions, but with a less clear time frame to death. Consultation with palliative care specialists offers patients a mechanism to discuss and review management of symptoms and medical interventions that patients desire or wish to avoid.

**Emergency Medicine and End-of-Life Care**

Emergency clinicians encounter death more frequently than other types of clinicians. Resuscitation and restoration to functional life is a primary goal of emergency practice, but seriously ill patients treated in the emergency department (ED) often present with important but less emergent complaints, and the emergency clinician often does have time to explore options for care with patients or family. Even when a patient has a severe chronic disease that is not curable, interventions are available that can improve the quality of life. Conversely, at the end of a course of chronic disease, death is not always unwelcome.

Addressing the needs of patients and their families in the ED at these critical times requires an important set of skills. In 2006, the American Board of Emergency Medicine joined with nine other specialty boards to cosponsor the American Board of Hospice and Palliative Medicine. This alliance has recognized the real need for emergency clinicians to address the wide range of interventions and management decisions that are relevant at the end of life. The integration of emergency medicine and palliative medicine has stimulated educational efforts to define the scope of ED-based palliative care and curriculum design. Some evidence has suggested that on average, palliative care and hospice patients may live longer than similarly ill patients who do not receive such care.

In caring for patients with serious life-threatening illness, a number of palliative care skills are required of the emergency clinician (Table e9.1). One important end-of-life skill is to determine the patient’s wishes for interventions in a time of crisis rapidly. These wishes may be transmitted through written advance directives or direct conversation with a patient or proxy about general values or specific management choices that should guide ED management. Invasive interventions may carry greater risk and less benefit near the end of life. The patient’s choices may include spiritual, economic, and community factors that the emergency clinician cannot know without clear rapid communication and the establishment of treatment goals. The national Education in Palliative and End-of-Life Care for Emergency Medicine curriculum has been designed to help emergency clinicians prognosticate better, convey medical and technical choices, and discuss goals of care with patients and families at these critical times.

Subspecialty palliative care is the care provided by a specialized interdisciplinary care team that is focused on the physical,
patients with serious and incurable diseases and manipulate the timing of death, and as people increasingly exercise their autonomy to decide how and when their dying should occur, more conversations occur about what constitutes a good death. There is evidence that the quality of life for persons who live into their 80s is better spiritual, and psychological support of patients and families living with serious life-threatening and or terminal illness and is compatible with patients seeking curative therapies. In 2013, the American College of Emergency Physicians published, as part of the Choosing Wisely Campaign, the recommendation that emergency clinicians should engage patients who present to the emergency department (ED) with chronic or terminal illnesses, and their families, in conversations about palliative care and hospice services. Early referral from the ED to hospice and palliative care services can benefit select patients resulting in both improved quality and quantity of life.

End-of-Life Trajectories

With modern medical advances, chronic diseases are present during the last years of life for most people. Three diseases—heart disease, cancer, and stroke—are responsible most deaths, with less than 10% being accidental. Four common trajectories of dying have been described (Fig. e9.1). Sudden death (due to cardiac arrest, trauma, or other sudden event) occurs in only 15% of people. The other trajectories are more common and occur with roughly equal frequency. The predictable decline in patients with terminal illness during 6 months or less provides the basis for the hospice concept of managing the dying process for patients with cancer and terminal AIDS. In cases of organ failure (eg, COPD, heart failure, renal failure, other progressive, serious medical diseases), gradual decline is punctuated by intermittent exacerbations (entry-reentry decline). The fourth trajectory of gradual decline, or frailty, is associated with some form of dementia in 50% of affected persons and a lingering course that can extend for many years, stressing and wearing out caregivers and other support systems as decline in functional abilities progresses. As technology gives emergency clinicians the ability to stabilize patients with serious and incurable diseases and manipulate the timing of death, and as people increasingly exercise their autonomy to decide how and when their dying should occur, more conversations occur about what constitutes a good death. There is evidence that the quality of life for persons who live into their 80s is better

*It is important to give the patient an opportunity to respond to each question. Follow-up questions and responses should be based on careful listening to the patient, with use of the patient's own words whenever possible. From Quill JE: Initiating end-of-life discussions with seriously ill patients: Addressing the "elephant in the room." JAMA 284:2502–2507, 2000.*
Goals of Care as Central to Emergency Intervention and Care Planning

Determination of the goals of care will dictate ED interventions and care planning. In a patient who lacks the ability for decision making, rapid determination of the patient’s or surrogate’s hopes and expectations for interventions based on the clinical scenario at a time of crisis is crucial. An ED visit alone does not suggest that patients or caregivers want interventions at the end of life, but they do want accurate medical assessment and guidance based on expert opinion. Previously stated wishes may be transmitted through written advance directives or direct conversation with a patient or proxy about general values or specific management choices that should guide ED management. The patient’s choices may include spiritual, economic, and community factors that the emergency clinician cannot know without clear, rapid communication and establishment of treatment goals.

Key components of goals of care conversations include sharing prognostic information, eliciting decision making preferences, understanding fears and goals, exploring views on trade-offs and impaired function, and wishes for family involvement. Emergency clinicians are not required to offer treatments that are not beneficial. Unfortunately, information available in the out-of-hospital setting or the ED is often insufficient for making a judgment that a particular patient’s condition is terminal or that treatment efforts would be futile. When cardiopulmonary arrest occurs, emergency clinicians proceed with full resuscitative measures unless there is a clear understanding that this is contrary to the patient’s wishes. Assessment of the goals of care and patient’s prognosis, once information is known, can guide the emergency clinician in determining if resuscitative efforts are not beneficial based on the goals of care.

Field Death Pronouncement

Several physiologic circumstances have been identified in which out-of-hospital providers should not initiate or continue CPR because of uniformly poor outcomes and no benefit from intervention. American College of Emergency Physicians (ACEP) and American Heart Association (AHA) guidelines state that CPR should not be initiated in patients with nontraumatic cardiac arrest and signs of irreversible death, such as decapitation, dependent lividity, or rigor mortis. ACEP policy recommends discontinuation of resuscitation in the out-of-hospital setting if the patient remains in asystole or wide-complex pulseless bradycardia after a trial of adequate resuscitation, including CPR, intubation, medications, defibrillation, and pacing. The National Association of EMS Physicians supports this approach. Termination of resuscitation efforts in nontraumatic cardiac arrest patients should be made in agreement with online medical direction and predicated on access to witnesses or family, provider comfort with death notification and grief counseling, and safety and logistic considerations.

In some systems, newer, physiology-based algorithms for the termination of resuscitation are being developed. If questions arise about resuscitation, CPR and advanced cardiac life support measures should be initiated and the patient transported. It can be easier and is ethically more sound to withdraw care in the ED than to withhold care at the scene.

Honoring Advance Directives to Withhold Resuscitation

Honoring patients’ wishes at the end of life should be a goal for out-of-hospital and ED personnel. Most out-of-hospital providers...
think that end-of-life skills are important; 93% of Oregon EMS providers have found POLST orders are helpful in the event of a prehospital cardiac arrest, and two-thirds thought they were useful in patients who were not in arrest.\textsuperscript{23} Significant gaps in training and knowledge about end-of-life issues have been noted among paramedics.\textsuperscript{24}

**Death in the Emergency Department**

**Delivering Bad News**

Every emergency clinician will be required to communicate bad news to patients, family members, and caregivers. The manner in which this is done may make a difference in the course of subsequent grief and coping. Compassionate communication can strengthen trust and foster collaboration between the medical team and patient and family. Emergency clinicians have particular challenges in delivering bad news. They do not have ongoing relationships with their patients, and the bad news may be abrupt and unexpected. However, sometimes the lack of a prior relationship allows a more frank and open conversation about a patient’s illness, prognosis, and wishes, particularly when the patient has a severe chronic disease.

The goal of skillfully breaking bad news is to reduce the severity and duration of stress and encourage engagement of coping mechanisms for emergency clinicians and for patients and their caregivers and family. Studies have shown that staff and clinician stress often peaks just before the transmission of the bad news, whereas patient or caregiver stress emerges after the delivery of bad news. Emergency clinician stress correlates directly with the severity of the news and feeling responsible for the outcome and inversely with the amount of experience in delivering bad news. Many emergency clinicians feel inadequately prepared for death disclosure or delivery of bad news about a new diagnosis or turn in health status for a patient with a life-limiting illness.\textsuperscript{25} Feeling skilled in providing disclosures to families is key in managing external sources of provider stress. Anticipatory stress of delivering bad news may be reduced by use of a structured protocol, with practice, and by being intentional about the physical and social aspects of the setting.

Several initiatives to improve the delivery of bad news have been introduced. These encourage training in communication skills, explicit instructional sessions, role playing, use of standardized patients, and observing colleagues who are comfortable with this aspect of patient care. However, the best methods of increasing patient and family satisfaction with this important aspect of patient care have not been examined. Emergency clinicians who insulate themselves from stress may inadvertently increase stress for the receiver, whose needs should be primary; emergency clinicians should avoid the use of vague language, delegation to others, and delaying or rapidly disengaging from the encounter.

For the patient and family, the ED is typically the place where bad news is sudden and unexpected, thereby making the strain even more severe and overwhelming. Trust between ED caregivers and critically ill patients or their survivors does not come easily. Whereas emergency clinicians may focus on the content of the information they should convey, patients focus more on the process. Surveys of patients and families have identified the following factors as desirable for receiving bad news: privacy when receiving news, ability to express emotions safely, information that is free of unclear language or medical jargon, empathic and caring attitude, allowance for hope, and ability to ask for and receive good medical information. One proposal for encouraging provider empathy is to structure a conversation according to the NURSE mnemonic—the provider names the emotions observed, confirms whether this understanding of the receivers’ feelings is correct, expresses verbal and nonverbal respect for the receivers’ feelings, supports them through expressions of concern, understanding, and willingness to help, and explores additional concerns.

The steps listed in Box e9.1 and explained in detail in the following paragraphs are designed to shape the interaction to facilitate the patient’s or survivor’s coping. This six-step template was adapted from Buckman’s work and adopted by the Education for Palliative and End-of-Life Care (EPEC) teaching project. Key to moving through the process of delivering bad news is the ask-tell-ask interactional framework, in which the emergency clinician is guided by the patient and family with regard to the pace, amount of information, and style that will work best to let them feel and hear what they need.

**Step 1: Clinician Preparation.** Before the emergency clinician interacts with the family or patient, preparatory steps are important. These include confirming all medical facts of the case, clarifying the name of the patient, being aware of any uncertainty about the patient’s identity, and knowing the relationships between the patient and those with whom one will be talking. The physical site for the conversation should be quiet and allow private exchange of information and safe expression of emotions. This is sometimes difficult in the ED, but a family room or other quiet area usually is available. If the patient can be included, moving the patient to a private area is helpful, or key members of the patient’s support group can be gathered around the bedside. Emergency clinicians should identify themselves and their position, directly address the patient (when present) or the key persons receiving the news, and refer to the patient by name. Before beginning the discussion, the emergency clinician should sit down close to the patient, make direct eye contact with the patient (or close relatives), and be physically and mentally open to their concerns and needs.

**Step 2: What Does the Patient Know?** It is useful to know what the patient or family understands before the delivery of news. An introductory question can be used, such as, “What do you understand about your illness?” or “What have you been told happened to [name of spouse, sibling, other]?” This information helps the emergency clinician to see the event as the patient and family are seeing it and to adjust the mode of delivering this news to their understanding. When patients and families may expect the worst, this tactic can be perceived as delaying the news. In a less critical situation, asking about previous testing, conversations with other emergency clinicians, and understanding of the patient’s illness can help the subsequently delivered information fit into the patient’s perspective and expectations.

**Step 3: How Much Does the Patient Want to Know?** Every patient has the right to accept or to refuse medical treatment...
on the basis of informed consent. This also is true for information. Most patients appreciate the direct simple truth about their condition and prognosis. There will, however, be some patients who do not want to receive the information themselves. These patients may wish to designate a friend or family member to represent them. This choice should be respected, if possible. People process information and make decisions in many different ways on the basis of their own cultural and religious views and previous experiences, and the Western principles of truth telling and individual decision making may be of lower priority to some families and communities.

Sometimes the family learns of a diagnosis and prognosis before the patient does and requests that the patient not be told. The emergency clinician’s alliance with patient and family is important, although responsibility to the patient is primary. Physicians should explore why families do not want the patient told bad news:

- Is it a cultural tradition?
- Are they afraid of what harm it will cause the patient?
- Have they had previous bad experiences?

The emergency clinician is still required to ask the patient how much he or she would like to know. Sometimes it is helpful for the emergency clinician to invite family members to be present for this discussion. Important information should be shared with the use of an independent interpreter—rather than a family member—if the patient does not speak the same language as the clinician.

Step 4: Sharing the Information. In general, patients and families want to know bad news in a timely fashion. This is sometimes uncomfortable, particularly when information is incomplete, a common occurrence in the ED. At the very least, it is recommended that patients and family be given a preparatory warning after introductions, such as, “I am afraid I have some bad news.” In delivering the information, it is important to use simple nonmedical language and make sure that the patient comprehends the information. Allow space for patients and family to absorb the news, react, and begin to ask questions. Typically the patient and family stress response will lag behind that of the emergency clinician because she or he has had at least a few minutes to adjust to the current situation, but the family has not.

Use of the phrase “I’m sorry” can be a reflection of empathy but, to avoid the implication that errors have occurred in treatment, some emergency clinicians have suggested the use of expressions such as “I wish things were different” instead. Survival data can sometimes be helpful, even when tentative. The emergency clinician’s message should include some realistic hope and reassurance that the care team will not abandon the patient, even when cure or survival is unlikely.

Step 5: Responding to Feelings. The reaction to bad news is often unpredictable and can range from sadness to overt anger. It is important for emergency clinicians to be aware of the wide variety of responses that will be seen. The patient and family should be allowed to express their feelings, even if this is uncomfortable. Acute grief is painful but important. The emergency clinician should be prepared for those who turn inward and those who rage outwardly. Practicing and reflecting on these situations will allow the emergency clinician to deliver bad news and support the survivors. In the ED, it is helpful to invite other members of the care team into this meeting (eg, social worker, nurse, chaplain), especially those who will not be pulled away, so they can provide emotional support and help the family navigate through the early stages of grief, as well as the necessary technical details.

Step 6: Planning and Follow-Up. The ED is an entry point into the hospital if the patient survives. Family members should be encouraged to stay with the patient, particularly if it is possible that the end of life is near. Prognosticating may be difficult in view of the limited information obtained in the initial assessment. When initial management has stabilized a patient with an acute critical turn, it may be appropriate to look ahead to decompensation, which may occur later in the hospitalization. Some experts have suggested a “hope for the best and prepare for the worst” framework for conversation. The emergency clinician can share the success, however transient, of any ED interventions and the positive news and hope that this provides. At the same time, he or she can prepare the patient or family for the possibility of later setbacks and have them consider what actions may or may not be appropriate if the worst happens. If the patient does not have written advance directives, the emergency clinician can facilitate the conversation, initiate written wishes, or at least advise the patient that the admitting physician will need to have an early conversation about future plans and goals for the patient. The emergency clinician should inform the patient and family of the next steps, including hospital admission or discharge from the ED, consultation with specialists, support group referral, and chaplain services. It is important to make sure that the patient and family do not feel abandoned. When dying is near, active care and comfort are important medical tasks for the care team.

Death Notification

One particularly difficult form of bad news is death notification. Several algorithms exist to assist emergency clinicians in learning the steps. Practice can help emergency clinicians perform this task more smoothly (Box e9.2). In general, the format can follow the guidelines for delivery of bad news from Box e9.1. With death notification, however, diagnosis is certain, and specific actions will be required. Families do not have time to adjust or to think about options, and the news cannot be softened.

Telling in Person. Death notification usually occurs after an unsuccessful resuscitation attempt. Emergency clinicians should be sure that they are presentable and wear a name badge. If possible, ascertain beforehand the names of the persons who will receive the notification, their relation to the patient, and what they know about the patient’s condition. Other members of the medical team may have met them already and can be a source of support.

**BOX e9.2**

**Elements of an Empathic Death Disclosure**

- Introduce self and role.
- Sit down.
- Assume comfortable communication distance.
- Use acceptable tone and rate of speech.
- Make eye contact.
- Maintain open posture.
- Give advance warning of bad news.
- Deliver news of death clearly (use dead or died).
- Tolerate survivor’s reaction.
- Explain medical attempts to “save” patient.
- Use no medical jargon; use language that is clear and easily understood.
- Offer viewing of deceased.
- Offer to be available to survivor.
- Conclude appropriately.

The Practice of Emergency Medicine

Telephone Notification. When the notification is to an individual who is more than an hour away or otherwise unable to come to the ED physically to receive the bad news, it needs to be given by phone. If the first contact with survivors of an ED death is by telephone, it is recommended that the survivor be told to come to the ED, if at all possible. Although family members may ask or even demand to know if death has occurred, allowing some time for the assimilation of news by delaying information about the final outcome may be more helpful for the grieving process. Nonphysician staff may be used to summon survivors and can inform them that the patient has been involved in an accident or is seriously ill without signs of improvement.

The emergency clinician should make sure that the relative has someone present in the room if possible, ask the relative to be seated, and name the person involved. It is best to start with brief information about the circumstances and provide a warning that bad news is coming before breaking it. Even a few seconds of preparation in these circumstances can serve to partially attenuate the acute psychic pain. As indicated by the perceived response, the clinician may need to ask, “Are you able to talk for a few minutes?” Some individuals may be unwilling or unable to continue after they hear the initial news, and they should be given an “out,” but a definite time to reconnect should be established (eg, 10–15 minutes). Long-distance loved ones cannot view the body to facilitate confirmation and acceptance and inevitably have questions not addressed in the initial conversation. The relative should be given a telephone contact of someone who actually provided care for the patient. Otherwise, if a relative calls back, lack of information about what transpired on a prior shift may cause frustration or even feed the person’s denial or false hope that the tragedy did not occur.

Viewing the Body

At some time immediately after death, the family should be offered an opportunity to view the body. This may be the first exposure to the body for the survivors and can make an abstract and unreal notification more concrete. Although most survivors find viewing of the body helpful, no attempt should be made to force this on them, and a few are not comforted by seeing the deceased.

If possible, the body should be moved to a small room, preferably away from the main treatment area. This not only ensures privacy but also makes the family feel more at ease. Family members should be warned of what to expect, such as color and temperature changes, injuries or invasive premortem procedures, and the presence of endotracheal and intravenous (IV) tubing or other medical devices.

A staff member should remain in the room or within close range at all times. This contact allows the staff to help make the viewing an important and supportive aspect of the grieving process. At times, it may be necessary to touch the body to assure the family that this is appropriate. Survivors should be allowed to remain with the body for as long as seems appropriate. When gross disfigurement has occurred, the viewers should be warned about this, and the body should be discreetly covered, when possible. Survivors may even find that helping to clean and prepare the body (particularly with a pediatric death), holding a loved one, or preparing for transport may allow a final expression of caring.

Family Presence During Resuscitation

It is increasingly common to invite a close family member to attend resuscitation attempts. Emerging evidence has suggested that presence during procedures and resuscitations may be beneficial to surviving patients and family members who choose to stay, and they are not harmed by the experience.30,37 Less consensus exists among providers, and they often express discomfort with the concept, with nurses expressing less discomfort than physicians.30,31 If resuscitation is to be witnessed by a family member, preferably a protocol is in place and a staff member who is dedicated to supporting that person should be present.1 Processes and procedures should allow for the ED team to work effectively but also allow families the option of observing resuscitation.

Goals of Care

Establishing Goals of Care. A core skill in managing patients near the end of life is the ability to assess and establish goals of care. In a true emergency, where the patient lacks capacity and there is no legal surrogate or advance care plan, such conversations take a back seat to resuscitation interventions. Most patients with a serious illness will present with enough time to assess goals of care before interventions are required. In the ED setting, several approaches can be helpful to establish which treatments patients prefer near the end of life.

Initiating a Conversation on Goals of Care. Emergency clinicians see many sick patients who do not have written advance directives but are stable enough to have meaningful conversations about their needs and goals, their perception of where they are in the course of their disease, whether they wish to cure an intercurrent problem, which symptoms require management, and how much effort they wish to have undertaken if resuscitation is needed to preserve their life. Patients with a seemingly lethal condition may be aggressively pursuing curative or at least disease-modifying options. Conversely, the burden of suffering that some patients are experiencing may not be obvious until they are asked specifically about their illness and wishes. With or without written advance directives, the emergency clinician needs to ask about the patient’s wishes. Key components of goals of care conversations include sharing prognostic information, eliciting decision making preferences, understanding fears and goals, exploring views on trade-offs and impaired function, and wishes for family involvement13 (see Table e9.1). The start of the goals of care conversation most naturally begins with an assessment of the patient’s global understanding of their illness, as well as their values (“What is most important?”), fears (“What are you most worried about?”), and expectations (“What are you expecting from your treatment?”)22,23 Any interventions need to be considered in the context of caring for the patient and enabling patients to achieve their goals. Common goals might be less interventions and desire to go home, life-extending interventions to buy time, with the understanding that this may limit other possibilities (eg, comfort or the ability to be at home), or the concept of the time-limited trial—try this to see if it can achieve goals and stop it if it cannot.24
Prognostication

Functional Status and the Value of the Surprise Question. ED patients invariably will present with signs and symptoms of deterioration, and the emergency clinician will need to formulate an opinion about where the patient is in their end-of-life trajectory. Common signs of deterioration include altered mental status, elevated heart rate or fever, and decreased oral intake. They may also present with an acute emergent condition such as acute myocardial infarction, stroke, or severe sepsis and will manifest multiple abnormalities, such as renal failure, electrolyte derangement, or infection. Patients, caregivers, and surrogates are typically frightened, confused, and chronically fatigued from the burden of illness. There may be those involved with home care systems that are in place, such as home health or hospice care, who may not understand the full nature of the patient's illness and life trajectory.

One way of formulating prognosis under these circumstances is the so-called surprise question235: “Would you be surprised if this patient died in the next _____ (hours, days, weeks, months, year)?” Those who are identified as not being surprised by a death within 1 year are appropriate for palliative care consultation that may occur in the ED, during hospital admission, or as an outpatient. Emergency clinicians may be hesitant to declare that a patient is in the last phase of decline from a terminal illness for fear of being wrong, but studies have shown that they are relatively accurate in formulating an accurate prognosis. Prognostic formulation should be done by using the time frames of hours to days, days to weeks, weeks to months, or months to years.

Functional Status in Relationship to Prognosis. In the context of limited information, functional status prior to ED presentation is the best predictor of postpresentation intervention outcomes. Prognostication in noncancer conditions remains complex but correlates with functional status.21 Standard functional assessment is measured in oncology patients with the Eastern Cooperative Oncology Group (ECOG) scale and in non-oncology patients with the Karnofsky Performance Scale (KPS; Table e9.2). Cancer patients with an ECOG score of 3 or 4 (capable of only limited self-care, confined to bed or chair more than 50% of waking hours) have a limited prognosis and are typically not recommended to have cancer-directed therapies; instead, they should have treatment aimed at symptom management.

At the bedside, ask the key questions: “Tell me how you (your) loved one has been doing the last week or two? What have they been able to do for themselves? How much time do they spend up and out of bed in a day?” A patient who has metastatic cancer with brain metastasis, with relatively no symptoms, good functional status, and an acute sepsis presentation, is clinically distinct from the same patient who has been in bed for several weeks who has poor oral intake and is asleep for many hours of the day. In the former scenario, the patient is more likely to recover to hospital discharge with life-sustaining interventions such as antibiotics, vasopressor support, and intensive care unit admission than the latter. If not recognized in the context of normal progressive decline punctuated by a terminal fulminant event, the ED course may include comprehensive evaluation such as laboratory tests, IV fluids, radiographic evaluation, and emergent intervention, despite the patient not wanting these measures. Emergency clinicians should communicate where a patient is in the terminal illness trajectory, calm fears and anxieties, and create an emergent and contextually appropriate care plan.

Treating Symptoms Requiring Palliation at the End of Life

When a patient is suffering from a disease that is not curable, he or she may still want a variety of medical interventions as part of care, such as antibiotics for intercurrent infections, drainage of effusions that cause shortness of breath, wound care for decubitus ulcers, decompression of bowel obstructions, and pain management. The caregiver may encounter several unfamiliar principles when treating symptoms in someone near the end of life. One of the challenges for the emergency clinician is the treatment of symptoms without diagnosis of the underlying cause, even though this often is the appropriate option in palliative care. The emergency clinician may have concerns about drugging patients or overtreating them, but these are mostly unwarranted. Worry about unintended consequences may lead to underdosing of medications, leaving patients without desired relief. Concerns about respiratory depression arise when opioids are used, even

though the risk of respiratory depression is minimal when the dose is titrated to the patient’s desired endpoint.

Pain

Pain is a common complaint with terminal illness, although typically considered in the setting of cancer, pain in the end-of-life phase is prevalent across many noncancer conditions, such as heart failure, COPD, and dementia. As patients become less mobile, they may suffer pain from contractures, wounds, or other conditions secondary to the primary illness. Patients suffering from malignant pain may need continuous infusions of opioids to obtain relief or rapid titration protocols, as well as an adjustment of chronic doses of analgesics in the ED.41 Opioid use is appropriate for patients presenting with acute pain or chronic pain of moderate intensity (rated 5/10 or above; see Chapter 3). Obtain a thorough medication history to determine tolerance and dose adjustments that may be needed. Pain assessment is distinct for patients with chronic pain because they may not have abnormal vital signs or outward expressions of discomfort commonly observed with acute pain. Patients with advanced illness and pain may be tolerant to opioids and require high doses to achieve comfort. This may cause discomfort on the part of the provider.

Although not uniformly available, palliative care consultation can be helpful in guiding the treatment of malignant pain. Emergency clinicians should have a basic knowledge of how to treat severe pain at the end of life. Rapid opioid dose escalation is the most important intervention in cancer patients receiving opioids. Doubling the dose may be required until successful analgesia is reached. With IV administration of morphine, serum levels will be maximal in 5 to 15 minutes, so patients need to be reassessed and redosed promptly. Providing a stable analgesic effect is important; this is done by providing a long-acting formulation (eg, MS Contin) along with an immediate-release, short-acting agent for breakthrough pain. Side effects from opioids should be anticipated. Rising serum levels of opioids may stimulate the chemotactic trigger zone, causing nausea. Educating the patient that nausea will subside within days is helpful. Minimizing fluctuations by the use of long-acting agents, whenever possible, can limit this form of nausea. Constipation is a common effect of opioids, and tolerance to this symptom will not develop. Prevention is far easier than treatment, so a stimulant laxative should be part of all opioid prescriptions for malignant pain. The use of nonsteroidal antiinflammatory drugs may be helpful in potentiating the effects of opioids in cancer patients. Neuropathic pain can be treated with medications such as gabapentin. It is important to explain the proposed treatment plan clearly to the patient and caregivers, monitor the response to treatment and side effects, and coordinate changes in treatment regimens with the primary care physician.

Shortness of Breath

Dyspnea is a common symptom at the end of life. It is multifactorial and not defined by direct pathophysiology.29,30 Shortness of breath can be part of the last stages of airway disease, cancer involving the lungs, or other advanced chronic diseases as patients become cachectic and immobile. Although the cause may not be found, several treatments may be helpful. Oxygen therapy is not harmful but may have limited effects.80 In the actively dying patient, morphine and atropine can be used to dry secretions, slow breathing rates, and decrease the work of breathing. A safe starting dose of opioids for dyspnea is morphine, 2 mg IV q15min (or the equianalgesic equivalent of another opioid).41 Shortness of breath is often accompanied by anxiety. Benzodiazepines are not recommended for dyspnea as a first-line treatment and have been shown to cause increased morbidity in dying patients.82

Imminent Death

Patients facing imminent death often present with dyspnea, pain, and delirium. All are typically frightening for patients, caregivers, and surrogates. Signs of imminent death include irregular breathing, altered mental status (eg, agitation, stupor, coma), and/or mottling of extremities, with increased heart rate, increased temperature, or inability to handle secretions (death rattle). Although there is no evidence that secretions at the end of life are uncomfortable to patients, families are quite disturbed by them. In a patient who appears to have hours to days to live, the emergency clinician should consider initiating a goals of care discussion with a recommendation for hospice care, consultation with palliative care in the ED, and use of any ED resources to provide spiritual and psychosocial support to the patient and family. End-of-life symptom management includes medications for pain, dyspnea, delirium, and secretions. Non symptom management includes discontinuation of monitoring and consideration of oxygen therapy and IV fluids, when indicated.

Hospice Care and the Emergency Department

Hospice as a Care System

Hospice care is a set of services provided in the home, free-standing inpatient facility, hospital, or nursing home. Some hospice companies use wards or units within the hospital setting, and others use beds dispersed throughout the hospital; some use both. Hospice services are delivered by an interdisciplinary team. All patients enrolled in hospice care have a supervising physician who authorizes the medical plan of care. On a daily basis, the hospice field teams may consist of registered nurse case managers, certified nursing assistants, social workers, chaplains, and volunteers. After a physician certifies that a patient is hospice eligible, that physician may choose not to retain responsibilities for the patient and instead transfer care to the medical director or another physician in the hospice facility. Although physicians may believe that they are acting in the best interest of the patient, this transition may make the patient and family feel that they have been abandoned. When a patient is receiving hospice care, the patient and surrogates agree that the goal is comfort care and that any services the hospice is expected to pay for must have prior approval of the hospice. If the hospice authorizes transfer to an ED for care, the hospice will usually cover all ED services. If a patient unilaterally decides to seek emergency services without partnering with the hospice, the patient may be at risk of losing hospice services because the hospice agency is the care plan manager.

Election of hospice care is not synonymous with “do not treat.” Patients receiving hospice care frequently are treated for infections, receive artificial nutrition and hydration, undergo palliative invasive interventions aimed at improving quality of life, or receive palliative disease-directed therapy (eg, chemotherapy, radiation, home vasopressors, transfusion). These interventions need to be assessed and recommended based on the goals of care assessment. If not available to the hospice directly, arrangements can often be made under contractual relationship for the care to be provided. It does require that the hospice agency be involved in any changes to the care plan. Palliative care consultants may assist in negotiating goals of care or coordinating care.

Evaluation and Management of the Patient Enrolled in Hospice Care

Patients enrolled in hospice care may present to the ED for a variety of reasons, including panic regarding decline, uncontrolled symptoms, inability or lack of the hospice agency to respond to
quickly if enrolled. Despite patient or caregiver perceptions, giving up, and patients and caregivers may fear that they will die be difficult for some patients and families to accept the comfort to call hospice before going to the hospital, this does not always desires hospice care. Although patients and families are instructed families, the ability to avoid a regular hospital admission and its referred to hospice from the ED. Because of the 24/7 nature of assessed to be comfort-oriented in nature, and in collaboration with the patient’s treating physician, should be considered for referral to hospice from the ED. Because of the 24/7 nature of hospice care, all hospice agencies typically have on-call staff that who presents to the ED.

Hospice Referral From the Emergency Department

Patients with a prognosis for death within 6 months or less if the disease runs its usual course, whose goals of care have been assessed to be comfort-oriented in nature, and in collaboration with the patient’s treating physician, should be considered for referral to hospice from the ED. Because of the 24/7 nature of hospice care, all hospice agencies typically have on-call staff that can be reached at all hours; many of them can respond to the needs of the ED for emergent admissions. For some patients and families, the ability to avoid a regular hospital admission and its associated risk of a hospital death can be very meaningful. Increasingly, hospices have hospital-based services that are open to ED admission. Steps for referral to hospice care for patients who present to the ED who have not been previously enrolled in hospice care are suggested in Boxes e.9.4 and e.9.5.

KEY CONCEPTS

- Palliative care is a physical, spiritual, psychological, and social support provided to patients and families at any stage of serious illness.
- Palliative care teams are specialized interdisciplinary teams that should be involved early in the course of illness.
- Hospice care is a care system for patients and families with a prognosis of 6 months or less if the disease runs its usual course; referral from the emergency department (ED) may be indicated.
- Patients at the end of life general follow one of four terminal illness trajectories: sudden death, organ failure, cancer, or frailty.
- Functional status is a strong predictor of decline and progression to death in patients with advanced illness.
- Goals of care conversations that outline patient and family hopes and expectations of interventions should be carried out.
- Emergency clinicians should make recommendations for care plans, interventions, and treatment courses based on prognosis, goals of care, and expected benefit to meet the identified goals of care.
- Key communication skills include breaking bad news, death disclosure, and assessment of goals of care.
- Interpretation of an existing advance care plan or receipt of a prehospital order (eg, POLST—Physician Orders for Life-Sustaining Therapy) should factor into ED treatment plans in the context of the patient’s illness trajectory.
- Advance care planning may occur in the ED in the form of goals of care assessment followed by recommendations and orders placed by the emergency clinician to implement the plan.
- Symptom management is critical at the end of life; common symptoms are dyspnea, pain, delirium and agitation, and secretion management.

Management of Patients Receiving Hospice Care Who Present to the Emergency Department

1. Notify hospice staff as soon as possible. Under the Medicare Hospice Benefit, hospice agencies are legally and financially responsible for the patient’s plan of care and all medical costs related to the terminal illness.
2. Determine the trigger for the ED visit, paying attention not only to the distressing signs and symptoms but also the emotional and psychosocial issues. Involve social services and chaplaincy personnel early if needs are identified. Contact the palliative care team for consultative advice if needed.
3. Treat distressing symptoms.
4. If deterioration is imminent and rapid decisions are needed regarding the use of life-sustaining treatments (eg, intubation for respiratory failure), a focused discussion around goals of care should occur in the ED.
5. If the patient is actively dying provide symptom management and spiritual (eg, call the cleric or lay representative) and social support.
6. Laboratory and diagnostic tests should be limited or withheld until discussion with the patient’s hospice care team. Testing should be based on patient-defined goals of care. Generally, low-burden, noninvasive methods that may reveal reversible pathology or clarify prognosis should be used first.
7. Therapeutic modalities should be based on patient-defined goals of care rather than automatic ED indications (eg, antibiotics for pneumonia should only be used if they meet a patient- or surrogate-defined goal of care).
8. Disposition should be planned after discussion with hospice staff based on the patient’s goals. Returning home or a direct admission to an inpatient hospice facility may be the best disposition, rather than hospital admission. At times, hospices can arrange 24-hour professional support in the home for patients with difficult to manage symptoms who wish to remain home.
9. Notify the inpatient palliative care service if the patient is to be admitted to the hospital. Hospice agencies may revoke a patient’s enrollment in hospice care if care goals have changed or may continue a patient under hospice care during an admission for palliation.

BOX e9.5

Initiation of a Hospice Referral From the Emergency Department

1. Assess Medicare Hospice Benefit eligibility.
2. Discuss hospice as a disposition plan with the patient’s physician. Contact the patient’s personal physician—discuss the current condition, prognosis, and prior goals of care conversations. If you are considering hospice care, ask if the physician is willing to be the following physician for hospice services.
3. Assess whether the patient’s goals are consistent with hospice care. Generally, this means a patient wants medical treatments and other support aimed at alleviating symptoms and maintaining quality of life, without life prolongation.
4. Introduce hospice to the patient and family or surrogates.
   • Discuss the core aspects of hospice care and how these features can help the patient and family (eg, 24/7 on-call assistance, home visits for symptom management, coordinated care with the patient’s physician, emotional and spiritual or religious support).
   • Address concerns and clarify misconceptions.
   • Phrase your recommendation for hospice care in positive language, grounded in the patient’s own care goals: “I think the best way to help you stay at home, avoid the hospital, and stay as fit as possible for whatever time you have left is to receive hospice care at your home…”
   • Discuss the location of hospice care. Usually, this is the patient’s residence, such as a private home or long-term care facility. Direct admissions to hospice facilities can occur depending on bed availability and ability of local hospice agencies to arrange an immediate, direct facility admission. This is not available in all communities and requires a discussion with the hospice agency.
5. Make a referral and write orders.
   Call a hospice agency; anticipate these questions:
   • What is the terminal illness? Who will be the following physician (step 2)?
   • What equipment will be needed immediately (eg, home oxygen)? Is there a caregiver at home?
   • Code status (patients cannot be denied hospice enrollment if full code; however, the hospice team will need to know if code status needs to be addressed further).

Questions you need to ask the hospice agency include the following:
• How soon can you make an intake visit to the patient’s home? Can you visit the patient immediately, even in the ED? (This is available in some communities.)
• How should I coordinate filling of new prescriptions I want the patient to have?

Examples of ED-initiated hospice referral orders:
• Evaluate and admit or enroll in hospice care.
• Terminal diagnosis:
• Expected prognosis—terminal illness with less than 6-month survival likely if disease runs its normal expected course (or be more specific, if indicated).
• Physician who will follow patient:

6. Ensure patient or surrogate understanding and secure the plan. Communicate the plan following ED discharge; provide the name and contact number for the hospice agency.

7. What if hospice enrollment is appropriate, but cannot be arranged in a timely manner? If the patient can be cared for at home safely for 1–2 days without extra services, send her or him home with appropriate prescriptions and care instructions. In most communities, patients can be enrolled in hospice care within 24–48 hours, even on weekends. If they cannot be cared for safely at home, observation versus inpatient admission is likely necessary until a safe discharge plan can be established.

9. Romem A, Tom SE, Beauchene M, et al: Physician who will follow patient: Contact the patient’s personal physician—discuss the current condition, prognosis, and prior goals of care conversations. If you are considering hospice care, ask if the physician is willing to be the following physician for hospice services.
CHAPTER e9: QUESTIONS & ANSWERS

e9.1. Which of the following is expected to be the least likely cause of death for adults in the United States?

A. Cancer
B. Cardiovascular disease
C. Heart disease
D. Trauma

**Answer:** D. According to the Center for Disease Control, accidents are the 3rd leading cause of death in the United States. [http://www.cdc.gov/nchs/fastats/leading-causes-of-death.htm](http://www.cdc.gov/nchs/fastats/leading-causes-of-death.htm)

---

e9.2. In a nondeath disclosure setting, deliverance of bad news should start with which of the following approaches?

A. Allowing the patient to react to the news
B. Asking the patient if he or she wants to know
C. Making sure you keep the conversation going to provide comfort and thereby dull the emotional impact of the news
D. Your knowledgeable of the complete medical implications and ramifications of the news

**Answer:** B. Respectful disclosure of breaking difficult news includes assessing the readiness and willingness of the patient to receive the news. Oncologist, 2006;5(4):302–11

---

e9.3. Mr. Jones is a 54-year-old man currently receiving hospice care at home for advanced colon cancer. His wife calls 911 when he becomes unresponsive. On presentation to the ED, his vital signs are blood pressure, 60/40 mm Hg; heart rate, 140 beats/min; temperature, 39.6°C (103.3°F); respiratory rate, 12 breaths/min. He is moaning with facial grimace. His wife, who is the legal decision maker, is at the bedside. Which of the following represents the best course of action?

A. Initiate sepsis protocol, begin treatment for pain, and call the palliative care service.
B. Initiate sepsis protocol, page the hospice nurse, and speak to his wife regarding goals of care.
C. Page the hospice nurse, begin treatment for pain, and speak to his wife regarding the goals of care.
D. Page the hospice nurse and speak to his wife regarding the goals of care.

**Answer:** C. Under the hospice benefit, the hospice agency is the care manager. The patient has lost capacity and his wife is his decision maker and she should be consulted regarding goals. Pain and non-pain symptoms should be addressed while other actions are being taken.

---

e9.4. Mrs. Smith is a 68-year-old woman with advanced heart failure who presents to the emergency department in cardiogenic shock with multiple previous admissions that state that she is currently optimized with all available therapies. You would like to initiate hospice care from the emergency department. Which of the following do you do next?

A. Call the hospice liaison on call for the ED to speak with her family regarding their options.
B. Call the palliative care service to discuss hospice care with the patient and her family.
C. Conduct a goals of care discussion with the patient and her amily.
D. Discuss the benefits of hospice care that would allow the patient to stay at home with her family.

**Answer:** C. Central to the discussion of hospice care is an assessment of the goals of care focused on care that addresses the distress of the illness and not the reversal of the primary illness.

---

e9.5. In performing a death disclosure, which of the following statements represents best practice when communicating news of death?

A. “Your loved one didn’t make it.”
B. “Your loved one has gone to a better place.”
C. “Your loved one didn’t make it.”
D. “Your loved one has passed on.”

**Answer:** B. It is not recommended to use euphemism or unclear statements to communicate news of death as this can cause confusion and ambiguity for the receiver of the news.

---

e9.6. Mr. Stone is a 27-year-old man with glioblastoma multiforme. He has completed radiation and is on oral chemotherapy. Over the last week, he has become progressively weaker and is now in bed. He is no longer speaking and is drooping things. He is taking sips of clear liquids and coughs after swallowing. Which of the following is the strongest predictor of his death?

A. Aspiration risk
B. CT scan that shows progression
C. Deterioration of speech
D. Functional status

**Answer:** D.
e9.7. Mr. Samuels is a 46 year-old man with severe breathlessness and anxiety due to advanced chronic obstructive pulmonary disease. His vital signs are temperature, 36.8°C (98.2°F); blood pressure, 110/60 mm Hg; heart rate, 115 beats/min; respiratory rate, 34 breaths/min; oxygen saturation, 98% on room air. He is visibly anxious and reports dizziness and dyspnea. Which of the following is the best initial treatment?
A. IV fluids
B. Lorazepam
C. Morphine
D. Oxygen

Answer: C. In the absence of hypoxia, morphine has been shown to relieve the sensation of breathlessness. Benzodiazepines have not been shown to relieve breathlessness and may increase side effects.

“Proactive Ethics”: How Can Emergency Clinicians Change the Rules?

A Global Perspective

KEY CONCEPTS

- Bioethics is a method of using values and moral principles to come to defendable decisions for ethical dilemmas.
- Ethical dilemmas arise from conflicts between multiple good options or multiple bad options, not between good and bad choices.
- Individual rights come from another’s duty to act.
- Values come from a variety of sources: community, culture, religion, and family.
- The values driving medical decisions should be the patient’s values.
- Basic ethical principles include autonomy, beneficence, nonmaleficence, justice, and confidentiality.
- In emergency medicine, caregiver safety is an important value.
- A rapid ethical decision tool: Is there an established precedent? If not, apply the following three tests: the impartiality test, the universality test, and the interpersonal justifiability test.
- Consent requires decision-making capacity or appropriate surrogate decision makers.
- Futility, although an appropriate reason for withholding nonproductive interventions, is not an excuse for withholding compassionate care.
- There are many areas of emergency medicine with unique ethical issues, such as resuscitation research, disaster response, morality of triage, response to high-risk situations, and wilderness medicine.
PRINCIPLES

The medical care we provide today bears little resemblance to what was available when the first edition of this book was published. What has not advanced as far or as fast is our system for deciding, in a moral and fair way, what treatments to provide. Scientific development has outpaced our social and ethical framework and often leaves clinicians struggling with moral dilemmas about the appropriateness of tests and procedures. This chapter is an introduction to our current tools for helping emergency clinicians approach ethical, rather than medical, dilemmas.

Definitions

Bioethics, a subset of ethics, is the application of values and moral rules to find reasoned and defensible solutions to actual or anticipated moral dilemmas facing clinicians. The moral precepts that underpin ethical decisions are derived from a variety of sources, including individual, cultural, and community value systems. Unlike the law, which is relatively rigid and can lag years or even decades behind modern developments, particularly in the case of scientific and medical issues, bioethical constructs allow a greater flexibility in decision-making. Emergency clinicians are often called on to identify a patient’s personal, cultural, religious, or community values and to balance these values with their own personal and professional ethos. A working knowledge of bioethics greatly enhances the emergency clinician’s ability to make reasonable, ethical decisions in the limited time frame common to the practice of emergency medicine.

In contrast to professional etiquette, which relates to standards governing the relationships and interactions between providers, bioethics deals with relationships between providers and patients, providers and society, and society and patients. Issues within the realm of professional etiquette include billing, referrals, advertising, competition, conflicts of interest, professional courtesy, and employment and supervision of auxiliary personnel. These are quite different from bioethics’ concerns of basic moral values and patient-centered issues. Although the two areas occasionally overlap, each relies on different standards, values, and problem-solving methods.

Ethics and Emergency Medicine

In emergency medicine, the focus is inevitably on the inherent “medical” nature of each case; therefore, it should come as no surprise that ethical dilemmas often go unrecognized. Emergency clinicians may also misperceive ethics as embodying the dictates of secular or religious law or as a discipline that describes irresolvable issues.

This chapter addresses a number of ethical issues in emergency medicine. What follows are brief discussions of the relation of law to bioethics; bioethical values and principles; moral imperatives in emergency medicine; ethical oaths and codes; applying bioethics to clinical situations; bioethical dilemmas in emergency medicine; a rapid decision-making model for ethical dilemmas; advance directives; the relationship between consent, decision-making capacity, and surrogate decision makers; ethical issues in resuscitation; and ethical issues in public policy.

BIOETHICS AND THE LAW

Basic Considerations

Emergency clinicians often look to the law for answers to thorny dilemmas. Yet, except in the rare cases of “black-letter law,” wherein specific actions are delineated, these issues are best served by turning to bioethical reasoning and using bioethics consultations. It is said that good ethics makes good law but that good law does not necessarily make good ethics. Societal values are incorporated both within the law and within ethical principles and decisions. Laws are rules of conduct established by legislatures, administrative agencies, courts, or other governing bodies. They often vary from locale to locale and are enforceable only in the jurisdiction where they prevail. By contrast, ethics is more universal within a culture, incorporating the broad values and beliefs of correct conduct. The primary differences between law and bioethics are shown in Table e10.1.

Modern bioethics developed because the law often has remained silent or inconsistent on matters vital to the biomedical community. The rapid increase in biotechnology, the failure of both the legal system and legislatures to deal with new and pressing issues, and the increasing liability crisis drove the medical community to seek answers to the difficult questions that practitioners have to work through on a daily basis.

Bioethical principles are not static and may evolve as societies change. The same evolution occurs within the law. For example, elective abortion, once illegal in most United States jurisdictions, is now legal in most circumstances and jurisdictions. Likewise, not all basic ethical principles have universal support, just as the values implicit in many legal changes have divided United States society.

Rights and Duties

Without a duty to act, there can be no rights. Both a moral and a logical connection exist between the rights and the duties of individuals; one cannot exist in the absence of the other. In general, a duty is an action required by the rights of others, the law, a higher authority, or one’s conscience. This obligation to act can be based on an individual’s personal values, professional position, or other commitments. For the physician, this duty to act is a role responsibility, at least specifically as a physician and possibly at all times. The role-duty link occurs whenever a person occupies a distinctive place or office in a social organization, to which specific duties are attached to provide for the welfare of others or to advance in some specific way the aims or purposes of the organization. In this circumstance, performance is predicated not on a guarantee of compensation but rather on a concern for
another person’s welfare. The emergency clinician has not only such a moral duty but, because of the Emergency Medical Treatment and Active Labor Act (EMTALA), also a legal duty.

Significant overlap can exist between legal and ethical decision-making. Frequently, there is concurrence on basic issues. On occasion, clarity within the law can lead to clearer thinking in bioethics, and vice versa. Both law and bioethics, for example, use the term rights, as in “patients’ rights” and “the right to die.” This term, often used to advance an ethical argument about medical care, frequently is misunderstood or applied erroneously. A legal right is a demand that a person can make on another person, embodied in in personam rights, or against the state for recognition and enforcement of this demand. Most rights involved in bioethical discussions are in rem rights. These most often are negative rights, because they entail someone else’s duty to refrain from doing something. A common source of ethical conflict is between “active rights,” the right to act or not act as one chooses, and “passive rights,” the right not to be acted on by others in certain ways.

**VALUES**

Values are the standards by which human behavior is judged. Values are learned, usually at an early age, through indoctrination into the birth culture, from observing behavior, and through secular (including professional) and religious education. Although many of these learned values overlap, each source often claims moral superiority over the others, whether the values are generic and cultural, legal norms, religious and philosophical traditions, or professional principles. Societal institutions incorporate and promulgate values, often attempting to solidify old values even in a changing society. In a pluralistic society, clinicians treat people with multiple and differing value systems, so they must be sensitive to alternative beliefs and traditions.

This section discusses the role of religious, patient, institutional, and professional values, including professional oaths and codes specific to emergency medicine.

**BOX e10.1**

**Commonly Accepted Moral Rules**

Moral rules govern actions on the basis of ethics and codes of conduct. These can justifiably be enforced and their violation punished. Although none of these rules is absolute, they all require one not to cause evil. Somewhat paradoxically, however, they may not require either preventing evil or doing good.

1. Do not kill.
2. Do not cause pain.
3. Do not disable.
4. Do not deprive of freedom.
5. Do not deprive of pleasure.
6. Do not deceive.
7. Keep your promise.
8. Do not cheat.
9. Obey the law.
10. Do your duty.

**Society’s Values**

Organized religions see themselves as keepers of society’s values. Even though various religions may appear dissimilar, most hold the golden rule, “Do unto others as you would have them do unto you,” as a basic tenet. Other moral rules that are common to most religions are listed in Box e10.1. Problems surface in trying to apply religion-based rules to specific bioethical situations. For example, although “Do not kill” generally is accepted, the activities that constitute killing, active or passive euthanasia, or merely reasonable medical care vary with the interpretation of the world’s religions as they do with the interpretations of various philosophers. As members of a democracy with significant populations practicing a number of religions, emergency clinicians should behave in a manner consistent with each patient’s values. The most basic underlying question is: What is the patient’s desired outcome for medical care?

Not only religious but also family, cultural, and other values contribute to patients’ medical care decisions. Without asking, it is impossible to know what decision a specific person would make. An important point is that religion influences modern secular bioethics, which uses many religion-originated decision-making methods, arguments, and ideals. In addition, clinicians’ personal spirituality may allow them to relate better to patients and families in crisis.

**Good Versus Evil**

The terms good and evil can be used to illustrate a stark dichotomy in ethical thought and values. The following is a current set of definitions that may help the physician find solutions to ethical problems. Good can be defined as what no rational person will avoid without a reason. Examples are freedom, pleasure, health, wealth, and knowledge. Evil can be defined as what all rational persons desire to avoid for themselves and for others they care about. Examples are untimely death, pain, disability, and loss of freedom or pleasure. Rational persons with deeply held religious beliefs may, for example, refuse a blood transfusion, choosing a likelihood of death over the permanent pain and anguish that they believe would ensue if they should violate their religious injunction. Conflicts that can be described as being between good and evil are not ethical dilemmas but rather moral temptations. Ethical dilemmas arise from conflicts between multiple good or multiple bad options.
Patient Values and Ethical Decisions

A key to making bedside ethical decisions is knowing the patient’s values. Many people cannot answer the question: What are your values? However, physicians can get an operational answer by asking patients what they see as their goal of medical therapy and why they want specific interventions. The responses represent concrete expressions of patient values. In patients who are too young or are deemed incompetent to express their values, it may be necessary for physicians either to make general assumptions about what a normal person would want in a specific situation or to rely on surrogate decision-making. But with patients who are able to reason and communicate, care should be taken to discover what they hold as their own, uncoerced values.

Although each individual is entitled and perhaps even required to have a personal system of values, certain values have become generally accepted by the medical community, the courts, legislatures, and society at large. Autonomy and individual dignity, for example, are two such values; they have been considered fundamental and often are given overriding importance. Although some groups disagree about each of these values, this dissension has not affected their application to medical care.

FUNDAMENTAL BIOETHICAL PRINCIPLES

Nonmaleficence and Autonomy

The basic tenet that all medical students are taught is nonmaleficence: “First, do no harm.” This credo, often stated in the Latin, primum non nocere, derives from the recognition that physicians can harm as well as help. With the physician’s fallibility recognized, patient autonomy is and has been for several decades the overriding professional and societal bioethical value. Autonomy recognizes an adult person’s right to accept or to reject recommendations for medical care, even to the extent of refusing all care, if that person has appropriate decision-making capacity. It is the counterweight to the medical profession’s long-practiced paternalism (or parentalism), wherein the practitioner determines what is “good” for the patient, regardless of whether the patient agrees. Coupled with paternalism is coercion, the threat or use of violence to influence behavior or choice. The August figure in white combined with implied or explicit threats remains a potent force for counteracting patients’ wishes. The thrust of modern bioethics is to respect patients by honoring their autonomy (Box e10.2).

Beneficence

At the patient’s bedside, beneficence (doing good) and confidentiality (holding information in confidence) have been long-held and nearly universal tenets of the medical profession. Similarly, personal integrity (the adherence to one’s own moral and professional standards) is basic to thinking and acting ethically.

Justice

The concept of comparative or distributive justice suggests that a society’s comparable individuals and groups should share similarly in the society’s benefits and burdens. Many society-wide decisions affecting thoughts and actions about the allocation of limited health care resources are based on this principle. Although it is important for physicians to be careful stewards of health care resources to maximize benefits, it is not appropriate for clinicians to limit or to terminate care on a case-by-case basis as an extrapolation of the perceived need to limit health care expenditures. Distributive justice is a social policy concept rather than a clinical model for individual physician/patient decisions.

BOX e10.2

Commonly Accepted Societal and Bioethical Values

Autonomy: Self-determination. A person’s ability to make personal decisions, including those affecting personal medical care. Autonomy is the opposite of paternalism.

Beneficence: Doing good. A duty to confer benefits. Production of benefit.

Confidentiality: The presumption that what the patient tells the physician will not be revealed to any other person or institution without the patient’s permission.

Distributive justice: Fairness in the allocation of resources and obligations. This value is the basis of and is incorporated into society-wide health care policies.

Nonmaleficence: Not doing harm, prevention of harm, and removal of harmful conditions.

Personal integrity: Adhering to one’s own reasoned and defensible set of values and moral standards.

Truth-Telling

Personal integrity involves adhering to one’s own reasoned and defensible set of values and moral standards and is basic to ethical thought and action. Integrity includes a controversial value within the medical community: truth-telling. Some people think that the patient has the right to know the truth, no matter what the circumstances, and have championed absolute honesty. Yet many of these same people, when patients themselves, have been appalled by their physician’s lack of sensitivity in relating unfavorable medical news. In this context, being honest does not mean being brutal; truth is best tempered with a modicum of compassion.

Physicians accept a lack of truth-telling, depending on the circumstances. When patient harm may result from failing to disclose the truth, such as happened in the infamous Tuskegee experiments, in which treatment was knowingly withheld from black men with syphilis, it is not only immoral but also probably illegal to withhold the information. Likewise, when failure to disclose information is strictly for the clinician’s benefit, such as not telling a patient about a dismal prognosis or a medical error, the clinician’s behavior suggests serious ethical and legal deficits. The issues become murkier when truth-telling, or lack thereof, involves a third party, such as a sex partner who has been exposed to an infectious disease.

Confidentiality Versus Privacy

Stemming at least from the time of Hippocrates, confidentiality is the presumption that what the patient tells the physician will not be revealed to any other person or institution without the patient’s permission. Health care workers have an obligation (duty) to maintain patient confidentiality. On occasion, the law, especially public health statutes, may conflict with this principle, because they require physicians to report specific diseases, injuries and injury mechanisms, and deaths. The Health Insurance Portability and Accountability Act (HIPPA) of 1996, a United States federal law designed to protect patient information, however, takes the principle of confidentiality to the extreme, resulting, paradoxically, in greater difficulty in obtaining crucial information needed to treat emergency department (ED) patients.

Privacy, which is often confused with confidentiality, is the right of patients to sufficient physical and auditory isolation so that they cannot be seen or heard by others during interactions.
with medical personnel. ED overcrowding, patient and staff safety issues, and ED design limit patient privacy in many cases.

The increasing use of telemedicine to render advice and to guide procedures at remote sites also places a strain on both patient privacy and confidentiality. Suggested ethical guidelines for such practices can facilitate the use of these new technologies without sacrificing either patient rights or physician duties.

Another recent development has been filming of ED patients for public viewing. Such filming, whether for medical records, education, peer review, or “reality television,” encroaches on ED patients’ reasonable expectation of privacy and confidentiality, because the recording can easily be distributed or misused. Although good reasons exist to allow such filming with patient acquiescence, the standard is now to abstain from such filming for commercial purposes and to require patient or surrogate consent for educational purposes.

MEDICAL AND MORAL IMPERATIVES IN EMERGENCY MEDICINE

Professional Values

Emergency clinicians, in both the out-of-hospital and ED environments, operate with four imperatives: (1) to save lives when possible, (2) to relieve pain and suffering, (3) to comfort patients and families, and (4) to protect staff and patients from injury. All but the last of these are common imperatives of most other clinicians as well, although saving lives may occur more often and more dramatically in emergency medicine settings.

Safety: A Unique Value

The last imperative, safety, is nearly unique to emergency medicine. In both the out-of-hospital and ED settings, clinicians often encounter dangerous situations in which the environment, the patient, a friend, or a family member poses a threat. Violence against emergency care workers is well documented and unfortunately common. The ED routinely deals with psychotic and intoxicated patients and patients injured in human-on-human attacks, and those involved are often under extreme stress. Although most try to accommodate basic patient rights, clinicians’ priority must be their own safety and the safety of their co-workers. This priority does not imply that clinicians should ignore patient safety but only that they should first ensure their own safety if they or their colleagues are at risk.

CODIFYING PROFESSIONAL VALUES: ETHICAL OATHS AND CODES

Conflicting Principles

In the abstract, bioethical principles often appear simple. However, clinicians adhere not only to basic bioethical principles but also, at least tacitly, to a number of professional, religious, and social organizations’ ethical oaths, codes, and statements. This complexity can create a confusing array of potentially conflicting bioethical imperatives. Because bioethical principles seem to be neither universal nor universally applied, the principles that are most patient-centered normally hold sway.

Organizational and Institutional Values

Institutions, including health care facilities and professional organizations, have their own value systems. Health care facilities, although relatively well standardized under the requirements of regulatory bodies and government agencies, often have specific value-related missions. Religiously oriented or affiliated institutions may be the most obvious of these, but charitable, for-profit, and academic institutions also have specific role-related values. The values of professional organizations often are set forth in their ethical codes.

Professional Codes

Through the years, the medical profession has codified its ethics more rigorously than any other professional group, incorporating many standard bioethics principles into its ethical codes and oaths. For generations, the existing part of the Hippocratic Oath set the ethical standard for the medical profession. Yet its precepts clash with modern bioethical thinking, and many subsequent professional codes have included what may best be termed economic guidelines and professional etiquette, along with ethical precepts. Emergency clinician professional values have been incorporated into organization codes, such as the American College of Emergency Physicians’ (ACEP) Code of Ethics, and into a more personal oath developed by the Society for Academic Emergency Medicine.

Most modern ethical codes do not require a higher level of duty or commitment for members than the same basic moral behavior that is expected of society at large. In fact, many of the ethical issues that would seem to be important to medical specialties usually are not addressed in their codes. Even when topics of inter-professional interactions are excluded, existing medical professional codes differ markedly (Table e10.2). All, however, try to give a “bottom line”—that is, minimally acceptable—course of action.

APPLYING BIOETHICS

Emergency Clinician/Patient Relationship

The emergency clinician has a markedly different relationship with patients from that of other health practitioners, especially those providing primary care (Table e10.3). Emergency clinicians care for patients who are unfamiliar to them and to the institution. Practitioners who either know their patients or who care for them in less acute settings often have the time and the mechanisms to make sound ethical decisions, but emergency clinicians have more limited options. A suggested method for rapid, ethical decision-making in the ED setting is outlined in Figure e10.1 and discussed in a later section.

Recognizing Ethical Problems

Although physicians like to reduce all clinical situations to “medical problems,” today’s increasingly complex medical environment often produces problems that are inextricably intertwined with fundamental bioethical dilemmas. Some are obvious, but many are more difficult to recognize.

Prioritizing Conflicting Principles

Once such dilemmas are recognized, applying bioethical principles to clinical situations can be confusing. When two or more seemingly equivalent principles or values seem to compel different actions, a bioethical dilemma exists. This situation is often described as being “damned if you do and damned if you don’t,” in which any potential action appears, on first reflection, to be an option between two seemingly equivalent goods or evils. In the following real case, taken from the book Ethics in Emergency Medicine, the attending physician can be said to be on the horns of a dilemma (involving two prickly but seemingly equal choices): although only two options for action may be available, both options involve a number of conflicting bioethical principles.
CHAPTER 10
Bioethics

Questions patients' decision-making capacity when they attempt suicide. Such patients' actions seem to raise the question of whether, in fact, they have a right or an ability to be autonomous. This physician also believes strongly in beneficence—helping those in need, relieving pain, and saving lives when possible. Beneficence suggests two alternative courses of action: palliative care or therapeutic intervention. Merely using analgesics and other comfort measures will abet a suicide; initiating medical and surgical interventions will prolong a dying process that the physician's colleagues have found to be unresponsive to even palliative treatment. Which value takes precedence: patient autonomy or beneficence? If beneficence predominates, should it be aimed toward relieving suffering, prolonging life, or a third option that

**Case Example: Conflicting Bioethical Principles**

A 60-year-old man stabbed himself in the abdomen because of intractable pain from terminal pancreatic cancer, unrelieved by any medical therapy. A well-meaning friend, who happened to be in the house when the event occurred, called the paramedics, who brought him to the ED. Although the man will obviously bleed to death if he is not given aggressive care, neither the patient, who is still alert and oriented, nor his wife, who is present, wants any treatment other than pain control. A review of his chart confirms that his physicians are at a loss as to how to alleviate his pain and that he is expected to die within the next several weeks. The physician believes in respecting a patient’s autonomy yet usually

---

**MEDICAL IMPERATIVES AND BIOETHICAL DILEMMAS**

Clinicians have their own ethical values, as do professional organizations and health care institutions. Conscience clauses permit clinicians to “opt out” when they believe that they have a moral conflict with professionally, institutionally, or legally required actions. These conflicts, which may have a religious, philosophical, or practical basis, pose a barrier to use of the normal ethical decision-making algorithm. When such conflicts exist, it is morally and legally acceptable, within certain constraints, for the physician to follow a course of action based on his or her own value system. The constraint generally requires that timely and adequate medical care be provided for the patient, which may be particularly difficult to achieve in emergency medicine. When conflicts over values exist, however, it is essential for the practitioner to recognize the patient’s identity, dignity, and autonomy to avoid the error of blindly imposing personal values on another.

**Professional Value Conflicts**

The imperative to save lives causes the most conflict between emergency clinicians and other clinicians. Emergency clinicians recognize that some of the intubations and resuscitations that they perform will be unwanted by patients or surrogates. Nearly all emergency clinicians have on occasion been berated by an irate intensivist or private practitioner for resuscitating a patient “who should not have been resuscitated.” Nevertheless, the lifesaving imperative begins when the ambulance is called.

One classic dilemma is that posed by the exsanguinating adult patient, awake and still with medical decision-making capacity, who explicitly states a refusal to accept any blood or blood products based on religious beliefs. The physician, with a professional duty and moral commitment to preserve life, does not agree with the patient’s decision. Yet society (through the benchmark of court decisions) has repeatedly sided with the patient. In this case, the patient’s autonomy and right to practice his or her religion are recognized as the overriding values. The case becomes less clear when the patient does not have decision-making capacity, is a minor, or appears to be under external pressure to make a life-threatening decision.

Other examples of ethical problems and conflicts in emergency medical care include uncertainty about resuscitation efforts, especially when patients and families may not want such efforts; teaching, particularly in critical situations or using procedures performed on the newly deceased; emergency medical service (EMS) control, when administrative rules and good patient care conflict; helping others when one’s own life may be placed at risk; and patient access, such as limited financial and personnel resources in the face of obvious patient need. Even if these problems do not fit into the classic form of a dilemma, they may be recognized as bioethical problems, because they require the clinician to make a choice between two (or more) accepted values.

**RAPID ETHICAL DECISION-MAKING MODEL**

The rapid ethical decision-making method of ethical case analysis, described in Figure e10.1, is designed as a way of avoiding an ethically incorrect course of action for the emergency clinician in need of a fast answer to an ethical dilemma. A decision based on a known precedent—the first step—is the most productive way to use this method. However, such decision-making requires advance planning, in-depth reading, and thought regarding ethical
problems. Just as with the indications for any emergency procedure, emergency clinicians should at the very least be prepared with a course of action for the most common ethical dilemmas they may face in the ED.

Even the prepared clinician, however, can encounter cases without relevant known precedents. With no precedent to rely on and no way to "buy time," the practitioner should select a possible course of action and test it for ethical validity. In such instances, three tests—the impartiality test, the universalizability test, and the interpersonal justifiability test—can be used. The impartiality test asks whether the practitioner would accept this action if he or she were in the patient's place. In essence, this is a form of the golden rule. The universalizability test asks whether the practitioner would be comfortable having all practitioners perform this action in all relevantly similar circumstances. This involves generalizing the action to all colleagues and then asking whether a rule for the contemplated behavior is reasonable. The interpersonal justifiability test asks whether the practitioner can supply good reasons to others for the action. Will peers, superiors, or the public be satisfied with the answers? If the answer to the question posed in each of the three tests is affirmative, the practitioner has identified a reasonable probability that the proposed action falls within the scope of ethically acceptable actions.

ADVANCE DIRECTIVES

The ethical principal of patient autonomy is the foundation for a range of documents that outline what care a patient wishes to receive if he or she is no longer able or competent to directly communicate those values. The term advance directive describes several types of legal and quasi-legal documents. Advance directives are usually written to avoid prolongation of an inevitable, often painful or non-sentient dying process. However, they can also be used to instruct surrogates and the patient's medical team to "do everything," whenever possible. Advance directives include the living will, durable power of attorney for health care, prehospital advance directive (Box e10.3), and mental health advance directive. Do not attempt resuscitation (DNAR), do not hospitalize, and out-of-hospital DNAR orders are not considered to be advance directives but rather are physician orders, because they are not patient or surrogate initiated. All play a role in emergency medicine.

Advance directives, DNAR orders, and other end-of-life considerations are discussed in Chapter e9.

CONSENT, DECISION-MAKING CAPACITY, AND SURROGATE DECISION MAKERS

Respect for patients, the basis for patient autonomy, requires that adults consent before undergoing medical interventions. To give consent, they must retain decision-making capacity. When patients cannot make their own health care decisions, others need to make such decisions for them. In such situations, three questions arise:

- What does "consent" mean in the ED?
- How can clinicians determine when patients lack such capability?
- Who then makes the decision?

Consent

Patients can provide three forms of consent: presumed, implied, and informed. Many patients may provide all three types of consent at different times during a single ED visit. Because clinicians use all three types of consent in EDs, and all are ethically and legally valid, clarifying the differences between them is in order.

The concept of presumed consent most commonly applies when patients are informed of what will occur and they do not refuse treatment. They allow themselves to be rolled on a gurney to the radiology suite to have a urethral catheter placed, and they remain still while being sutured. The more dramatic ED scenario involving presumed consent is the arrival of moribund patients with grave, often unstable conditions for which a reasonable person would be expected to want treatment. In those cases, clinicians "presume" that rational patients would want treatment. A question that must be raised, however, is whether those patients would want interventions even in the absence of a reasonable chance for meaningful (from the patient's standpoint) survival. Futility often is discussed from the clinician's perspective (see the Futility section later in this chapter); whether patients would give consent in these circumstances raises the question from the more valid patient's perspective.

Implied consent is operative when patients actively cooperate with the procedure, such as when they extend the arm for phlebotomy or lift the blouse so that leads can be placed for electrocardiography. Working under presumed or implied consent does not signify absence of patients' concern about the procedure or its complications. Rather, patients may (1) believe they know enough about the procedure to permit it or to cooperate with it without further questioning, (2) be in a condition (eg, unconscious) in which they are unable to communicate, or (3) feel too afraid (eg, of the clinician or hospital authority) or uncomfortable (eg, because of a language barrier) to ask.

Informed consent assumes that a patient who has decision-making capacity (eg, has been given all pertinent facts about the risks and benefits of a particular procedure) understands the risks and benefits and voluntarily agrees to undergo the procedure. Even if a patient with decisional capacity does not ask about a complex or potentially dangerous procedure, the clinician is obligated to provide information about the associated risks and benefits, unless the patient specifically asks not to be told. In those cases, the patient should be asked if he or she would like a relative or friend present in the ED to be told. This person need not be the patient's surrogate but may later help explain what occurred to the patient.

Informed consent relates to both law and ethics. Respect for persons is the requirement's ethical bulwark; statute and common law provide the legal rationale. Clinicians have a professional and moral obligation to provide their patients with the information necessary to make informed decisions. Communicating honestly with patients so that they may participate in decision-making is a recent rather than historical imperative. On the basis of a respect for patients, this cooperative physician/patient relationship reverses the paternalism that, since Hippocratic times, has guided physician interactions with patients.

Virtually all states, either in statute or by common law, now require physicians to inform patients about treatment choices and the associated risks and benefits. The legal standard for the information provided is either the community standard (also known as the professional community standard or the reasonable physician standard) or the materiality standard (also known as the reasonable or prudent or subjective patient standard). The former asks: What would a prudent physician in the same community, with the same background, training, and experience, have disclosed to a patient in the same or similar situation? The latter asks: What would a reasonable patient in the same or similar situation need to know to make an appropriate decision?

Note that great variability exists in the legal requirements. For example, although most of the nation's EDs require informed consent for many regional anesthetic blocks, closed fracture reductions, abscess incision and drainage, lumbar punctures ("spinal taps"), injection of radiocontrast agents and radionuclides for radiography, and nonemergency thoracostomy (chest
tube placement), Texas statutes eliminate any requirement to disclose the specific risks or hazards before these procedures are performed.

**Decision-Making Capacity**

Many ethical dilemmas in emergency medical care dissolve on ascertaining the patient’s decision-making capacity, often linked with consent to (or, more commonly, refusal of) a medical procedure. A basic canon of both ethics and law, as stated by Justice Benjamin Cardozo, is that “[e]very human being of adult years and sound mind has a right to determine what shall be done with his own body.” These situations can often be clarified by an appreciation of what is meant by decision-making capacity and how it relates to consent.

Emergency clinicians must be prepared to decide quickly whether patients lack decision-making capacity. Although a lack of capacity is obvious in the unconscious or delirious patient, it often is less apparent when the patient remains verbal and at least somewhat coherent. Because such decisions in emergency situations are often time sensitive, unlike in other medical venues, bioethics consultations may not be readily available.

In clinical practice, the word *competence* is often used to mean *capacity*. *Competence* is a legal term and can be determined only by the court. *Capacity* refers to a patient’s ability to make decisions about accepting health care recommendations. Capacity is always decision-relative rather than global. Although an inebriated person can have the capacity to refuse to have a small laceration sutured, especially if there is evidence of prior refusal without remorse, the same person may not have the capacity to agree to an elective operation or to refuse to have an emergent lifesaving procedure or operation. To have adequate decision-making capacity in any particular circumstance, the person must understand the options, the consequences of acting on those options, and the costs and benefits of consequences in relation to a relatively stable framework of personal values and priorities (Box e10.4). Disagreement with the physician’s recommendation is not in itself grounds for determination that the patient is incapable of making a decision. In fact, even refusal of lifesaving medical care may not prove the person incapable of making valid decisions if it is done on the basis of firmly held religious beliefs, as in the case of a Jehovah’s Witness patient who refuses a blood transfusion.

**Surrogates**

If patients lack capacity to participate in some decisions about their care, surrogate decision makers should then become involved. In most locales, the patient’s advance directive may designate surrogates, or such persons or agencies may be detailed in institutional policy or law. Surrogates often include spouses, adult children, parents (of adults), and others, including the attending physician. On occasion, bioethics committees or the courts will need to intervene to help determine the decision maker.

Children represent a special case. Persons younger than the age of majority (or unemancipated minors) are usually deemed incapable of making independent medical decisions, although...
Surrogate Lists

If a patient lacks decision-making capacity and has no advance directive, many states stipulate that another person may automatically become the person’s surrogate. In practice, this almost always means that the patient’s spouse may act in that capacity. Some states now have a statutory surrogate list to simplify the process.

The most extensive of such lists, which has worked well for nearly two decades, specifies surrogates in the following order: spouse (not divorced or legally separated), a majority of the adult children who can be reasonably contacted, parents (of an adult), domestic partner, sibling, close friend, and attending physician in consultation with a bioethics committee.

Bioethics Committees and Consultants

Multidisciplinary committees have been developed in most large hospitals to consult on cases with bioethical dilemmas and may also participate in surrogate decision-making. These committees usually have three main functions. First, they coordinate education on bioethical issues involving clinical care for the committee members, hospital physicians and staff, patients, families, and the local community. Second, they help institute mandatory or suggested policies or guidelines for health care professionals regarding decision-making processes in problematic cases and resource allocation. Third, they consult prospectively and retrospectively on clinical cases and offer advice and conclusions to those directly involved, most often concerning the treatment or non-treatment of patients who lack decision-making capacity. Ethics committees usually do not act as the primary decision makers. Rather, the members serve as consultants, providing information, advising, and supporting the primary decision-making role of the patient/family/physician triad. A common consultation relates to urgent decisions about withholding, withdrawing, or continuing life-sustaining medical care. A large part of ethics committee work consists of clarifying the facts and fostering communication. In 1995, the Joint Commission (formerly the Joint Commission for the Accreditation of Healthcare Organizations [JCAHO]) began requiring hospitals to ensure that ethics committees perform their functions.

Emergency Clinicians

In the past, clinicians made unilateral decisions for their patients, regardless of whether the patients had the capacity to decide for themselves. This still occurs, of course, especially for the acute illnesses and unexpected injuries seen in EDs. If the patient’s decision-making capacity is questioned in the ED, the clinician is usually forced to make a decision without assistance. But when it is possible to buy time, clinicians should consult with colleagues and, if possible, the hospital’s bioethics committee (see Fig. e10.1). When making unilateral decisions, clinicians should recognize that they are not omniscient. Prognoses are often incorrect and medical knowledge is finite.

Courts

The courts often act as the final adjudicators of disagreements over medical care. They appoint legal guardians and, in a few select cases, set precedent that is followed as health law. The courts, however, usually are neither expeditious nor necessarily cognizant of bioethical principles. They are instructed only to follow the societal values codified in the law. Many courts have suggested that whenever possible, health care decisions should remain at the bedside rather than in legal chambers.

RESUSCITATION ETHICS

The most time-dependent of all activities, and arguably the best training periods in the ED, occur during resuscitations. The patients who require this care have implicitly been guaranteed that all appropriate medical knowledge and skill will be brought to bear in the attempt to save their lives. This implied promise leads to a dilemma. If the most proficient ED professional always leads
the resuscitations and performs procedures, the patient will receive the maximum beneficence, as well as nonmaleficence, as expected. Yet restricting ED practice in this manner also deprives future patients of trained clinicians who could bestow the same beneficence.

This controversy has raged for many years. The appropriate balance seems to be that training in EDs can ethically proceed, as it does in other areas of medicine, if safeguards are provided in the form of onsite supervision by experienced clinicians to ascertain that the patients receive the best possible and most appropriate care. It also has been suggested that medical students and residents be certified for cognitive and procedural skills in a manner similar to that of other hospital physicians. This certification would enable faculty to know when trainees are capable of performing resuscitations, as well as other medical procedures, on their own.

Rarely discussed, but a common practice in some teaching hospitals, has been the custom of allowing trainees with little skill or knowledge to learn and to practice procedures on those undergoing resuscitation only when a patient is deemed "unsalvageable." This practice does a disservice to the patient because prolongation of resuscitative efforts solely for this purpose may lead to a clinical state that prolongs dying. It also harms the family and society by making them pay for unnecessary procedures. (It may actually be less problematic to practice and to teach once a patient is dead, because the patient cannot be harmed and the family does not pay for these activities. See the Postmortem Teaching section later in this chapter.)

Futility

Emergency clinicians, nurses, and EMS personnel may, in some circumstances, believe that further medical interventions are "futile." Yet only three situations meet the most commonly accepted definition. The first such situation, which clinicians can identify in only a limited set of circumstances, is that in which the intervention is effective in less than 1% of identical cases, based on the medical literature. ED thoracotomy for blunt trauma is a well-documented example. Another common scenario with very low survival rates is that of the out-of-hospital cardiac arrest, either unwitnessed or in a patient who arrives from a long-term care facility. Individual clinicians should not rely on their own experiences to make such decisions, however, because they often are skewed owing to selective memory, limited numbers of similar cases, and other biases.

The second futile situation is physiologic futility, in which known anatomic or biochemical abnormalities will not permit successful medical interventions. Examples of such abnormalities generally accepted by EMSs as reasons not to intervene or to provide transport to hospitals are rigor mortis (muscle contraction after death), algor mortis (lowering of body temperature after death), burns so severe that the victim is beyond recognition, and injuries incompatible with life (eg, decapitation). These, along with prolonged normothermic resuscitative attempts without success or prolonged "down time" with an isoelectric electrocardiogram and pulseless electrical activity, are the criteria often used to help determine whether EMS personnel can pronounce death on the scene. In these instances, EMS need not expend valuable resources in a futile resuscitative effort.

The third situation is that in which the proposed intervention will not achieve the patient's goals for medical therapy in accordance with the patient's values. Recognizing this instance, the ACEP asserts, Physicians are under no ethical obligation to render treatments that they judge have no realistic likelihood of medical benefit to the patient. Because this course of action is based on knowing the patient's values related to medical treatment, it is necessary to have talked with the patient in advance (rare in the ED setting), to have received surrogate-supplied information or decisions, or to have access to the medical record. The danger is that differences in values between caregivers and patients may lead to overtreatment or undertreatment. Communication, if necessary with use of a third party, may help resolve these issues.

The futility concept should never be used to deny care to dying patients. Even terminal patients experience medical emergencies that require intervention. The goal is to ease pain and suffering. How that is accomplished depends on the patient, the medical condition causing discomfort, and the patient's value system.

Withholding Versus Withdrawal of Treatments

In emergency medicine, a significant difference rightly exists between the withholding and the withdrawal of life-sustaining medical treatment. The justification for this distinction stems, in part, from the nature of the practice of emergency medicine and the unique manner in which emergency clinicians apply many ethical principles. Because emergency clinicians often lack vital information about their patients' identities, medical conditions, and goals for medical treatment, withholding of emergency medical treatment is more problematic than is later withdrawal of unwanted or useless interventions. Owing to the nature of emergency medicine, in both out-of-hospital and ED settings, higher standards are required to withhold medical treatment than to withdraw it.

Physicians should begin or continue resuscitation of those patients who arrive at the ED without sufficient evidence to determine that the resuscitation effort will be unsuccessful. The only reason to withhold cardiopulmonary resuscitation (CPR) is the availability of clear evidence, such as a standard advance directive, that the patient did not wish to have this done or of clinical evidence that further efforts would be futile. Without such information, the presumption must be to intervene.

Once the emergency clinician obtains information confirming a patient's wish not to be resuscitated or indicating a medical condition not amenable to resuscitation, resuscitative efforts and other medical treatment may appropriately be withdrawn. This information may be obtained from an advance directive, a patient surrogate, recent documentation in the medical chart, or EMS communication detailing the failed results of the ongoing resuscitative effort. With rare exceptions, such as after failed suicide attempts, resuscitative efforts should be withdrawn when information is provided either that the patient did not want such efforts or that the patient's medical condition precludes success.

Many factors influence the potential success of resuscitative efforts, including time to CPR, time to defibrillation, cause of the arrest, presence of comorbid illness, pre-arrest clinical status, and initial arrest rhythm. No combination of these factors, however, clearly predicts the outcome.

Three special situations should be noted:

- Cardiac arrest from blunt trauma is nearly uniformly fatal, so little benefit derives from performing chest compressions for any extended period after the airway is secured.
- When health care resources are limited (eg, during disasters), available resources (eg, time, personnel, and equipment) should be devoted to treatment of those patients with the greatest chance of benefiting. This principle may lead to withholding or more rapid discontinuation of resuscitative efforts than is standard in normal practice.
- It is unethical to prolong resuscitative efforts to practice or to teach procedures or to complete research protocols.

Palliative Care

Although lifesaving medical interventions may not be appropriate in all cases, emergency clinicians, whenever possible, should
provide patients with palliative care. Terminally ill and fatally injured patients have the right to receive state-of-the-art palliative care. Palliation often includes analgesics and may include diuretics, sedation, oxygen, paracentesis or thoracentesis, and other medications or procedures to alleviate suffering. Medical personnel should never withdraw or withhold care; only treatment should be withheld when it is appropriate. Although medical practitioners, surrogate decision makers, and sometimes patients find it emotionally easier to forgo new interventions than to withdraw ongoing treatment, no orders, policies, or directives should ever prevent emergency clinicians from alleviating discomfort.

The purpose of palliative interventions is not to prolong the dying process but rather, when death is inevitable, to make it as comfortable as possible for the patient. As patient advocates, emergency clinicians may need to “push” to have the patient admitted to a hospital, hospice, or nursing home or to get ancillary personnel (e.g., social workers, home health nurses) to intervene for the patient.

**Notifying Survivors**

Death, especially when it is sudden and unexpected, shocks and devastates family and friends. For them, it is a life-changing event, with every nuance burned into their memories. Moreover, although they may not consciously acknowledge it, such losses may deeply affect ED personnel, despite their almost constant exposure to life's disasters. This makes death notifications and dealing with the survivors both vital and extremely difficult. Emergency clinicians, who deal with sudden death on a regular basis, are in a position to gain considerable knowledge of and to hone their skills in how to care for the survivors, their newest patients.

Even though notification of survivors of a sudden, unexpected death is one of the most difficult parts of the job for emergency clinicians, they and other professionals whose job includes delivery of such news are rarely taught the skills necessary to perform this task. Notification of survivors is emotionally draining; 70% of emergency clinicians find death notifications to be personally difficult. Perhaps this is because only half received any type of death-notification education in medical school, and only one-third received any such training during residency.

On occasion, physicians give the job of death notification to residents, medical students, or nurses. Although all three groups should be present to learn the techniques involved, to have an opportunity to hear what is said, and to observe an attending physician showing sensitivity, they should not be left to do death notifications on their own. That is a form of professional abandonment and, in a teaching hospital, the worst form of student abuse.

**Viewing of Resuscitations**

Traditionally, survivors have not been permitted to view resuscitation attempts. That attitude, however, is gradually giving way to a more enlightened view based, in part, on recognition that families gain enormous psychosocial benefits from being present and that they are also patients in need of appropriate support.

The argument against allowing survivor onlookers has been that resuscitations often involve large teams, unclear communications, and team leaders who are unwilling or unable to make firm, timely, and rational decisions. Having family members present, the argument goes, introduces the possibility of an onlooker fainting or otherwise becoming another patient. Survivors frequently misinterpret the team's discussions or actions, and team members may feel uncomfortable having family members judging their actions.

Yet studies in both the United States and Britain have shown that nearly all survivors who witnessed ED resuscitative efforts found the experience helpful. Seventy-six percent of survivors responded that their grieving was facilitated by having witnessed the resuscitation, and 64% thought that their presence was helpful to their dying family member. Psychological tests of survivors who witnessed resuscitation attempts, performed at 3 and 9 months after the event, showed that this group experienced fewer episodes of "intrusive imagery," such as flashbacks of the events leading to the death, compared with survivors not present at the resuscitation (relatives in the control group). They also had lower levels of anxiety, depression, post-traumatic avoidance behavior, and grief.

The American Heart Association (AHA) now endorses giving family members the opportunity to be present so long as the patient has not previously objected. This position stems from the benefit families can derive from their presence during resuscitation attempts, the lack of harmful effects on them from viewing these resuscitations, and their quasi-right to be there based on the nature of their relationship to the patient.

The presence of these survivors does not hinder the resuscitative efforts and often leads to quieter, more effective team efforts. Experience has shown that survivors who witness ED resuscitative attempts never question whether the team "tried hard enough," do not ask whether the person is really dead, and spend less time in the ED trying to come to terms with the death. In addition, survivors may actually thank the ED team for their efforts, a situation that rarely occurs under other circumstances, and the ED staff never has to "notify" survivors of the death.

The general procedure is as follows:

- Ask survivors if they want to view resuscitative efforts.
- If they do, give them a quick briefing about what they will see, and have a knowledgeable staff member, usually a chaplain, social worker, or ED nurse who can answer their questions, accompany them.
- Provide a chair for elders and allow survivors to leave and to re-enter as they wish.
- Staff should attempt to cover as much of the patient as is compatible with effective resuscitative efforts.
- Team members should be advised that family is in the room.
- The survivors should be encouraged to talk to and to touch the patient.
- Decisions to pronounce the patient dead, although often discussed with the family, generally are communicated in the format of advising them that "we must stop now." They should never be asked whether to stop the resuscitative effort; this is a medical decision.
- If the family is present when it is clear that resuscitative efforts should cease, the situation should be explained to the family before supportive measures are discontinued. This provides them with a chance to “say good-bye” before death is pronounced. Dedicated pediatric EDs and pediatric resuscitation units in general EDs have adopted these procedures more often than others.

**Postmortem Teaching**

A less commonly discussed aspect of emergency medicine education programs is the use of recently deceased patients to teach or to practice emergency procedural techniques, such as intubations and central line placement. Although whether this practice is ethical is a matter of controversy, a reasonable argument might be that if medical treatment could not save the patient, then the emergency clinician’s responsibility is to hone skills for the next patient in need of expertise in resuscitative techniques. This is not to condone the desecration of a body. Rather, it suggests that because clinicians learned the techniques used during the attempted resuscitation on other dead or living patients, this...

PUBLIC POLICY AND BIOETHICS

Restricted Access to Emergency Medical Care

Society has acknowledged its moral obligation to ensure that
everyone has reasonable access to adequate health care. People’s
need for health care is unequally distributed and highly unpre-
dictable. Few could afford this care if left to their own devices, so
mechanisms are in place to share the risk.

The ethical dilemma for emergency clinicians comes in basi-
tically two forms: one precipitated by the institution in which the
ED is housed and one by outside third-party payers. Some institu-
tions have refused care to patients coming to the ED, sending
some away for clinic appointments at a later time. Institutions also
have pressured emergency clinicians to limit treatment, ancillary
tests, or hospital admission for patients without the ability to pay.
Although such limitation may seem patently immoral, another
question should be asked: Is there a moral obligation to the com-

The ethical and legal basis for these regulations is presumed
consent: If the research is not harmful and especially if it is
potentially helpful, most “reasonable” patients would acquiesce
to the research, given the basic values of good and evil (see Box
e10.1). As routinely occurs in emergency medicine practice,

Availability of Resources

Most triage systems are designed to serve the values of human
life, human health, efficient use of resources, and fairness. Never-
theless, because of the variety of specific triage settings and goals,
no single “correct” way to perform or to justify triage can be
identified. Routine triage in the relatively resource-rich setting of
the modern hospital ED, for example, focuses appropriately on
maximizing benefits for each individual patient, giving treatment
priority to patients whose needs are most urgent. In triage after a
massive disaster, when not all individual needs for lifesaving care
can be met, the focus may shift from an individual to a group
perspective, and triage officers may seek to save as many lives as
possible with the limited resources at their disposal. In special
circumstances (eg, times of war), military commanders may direct
that triage systems devote scarce medical resources to achieve a
nonmedical goal, namely, military victory. In situations of com-
plete devastation, the lack of social order and minimal resources
may make triage impossible.

Whether the choice of a triage system is justifiable depends on
an evaluation of the specific system itself, its underlying values
and principles, and the setting in which it is applied.

Resuscitation Research

Physicians in a new and advancing specialty have an obligation to
advance the knowledge base from which they practice. This can be
done only through research, a significant component of which
should necessarily be clinically based. In the United States, federally
mandated institutional review boards (IRBs) must approve any
research involving human subjects, including research in EDs and,
possibly, in prehospital care. Increasingly, research ethics commit-
tees are being used to approve human subject research throughout
the world. The IRBs try to guarantee that patients who are asked
to participate in research review and sign an adequate informed
consent document. Yet, even if the patient is conscious, it is unclear
whether truly free and informed consent can be given in the midst
of a medical emergency. In both trauma and cardiac resuscitation
research, informed consent is, of course, not feasible. It is usually
difficult, if not impossible, to obtain retrospective patient or, if
appropriate, prospective surrogate consent. So as not to deny criti-
cally ill and injured patients the opportunity to participate in
possibly beneficial research trials, the U.S. Food and Drug Admin-
istration (FDA) and the Department of Health and Human Services
(DHHS) issued regulations, which became effective in 1996, that
allow “emergency research” without informed consent. These regu-
lations contain extensive patient safeguards, including community
consultation, public disclosure, and intensive oversight.

The ethical and legal basis for these regulations is presumed
consent: If the research is not harmful and especially if it is
potentially helpful, most “reasonable” patients would acquiesce

to the research, given the basic values of good and evil (see Box
e10.1). As routinely occurs in emergency medicine practice,
persons suffering unexpected adverse events with a high proba-

Availability of Resources

Most triage systems are designed to serve the values of human
life, human health, efficient use of resources, and fairness. Never-
theless, because of the variety of specific triage settings and goals,
no single “correct” way to perform or to justify triage can be
identified. Routine triage in the relatively resource-rich setting of
the modern hospital ED, for example, focuses appropriately on
maximizing benefits for each individual patient, giving treatment
priority to patients whose needs are most urgent. In triage after a
massive disaster, when not all individual needs for lifesaving care
can be met, the focus may shift from an individual to a group
perspective, and triage officers may seek to save as many lives as
possible with the limited resources at their disposal. In special
circumstances (eg, times of war), military commanders may direct
that triage systems devote scarce medical resources to achieve a
nonmedical goal, namely, military victory. In situations of com-
plete devastation, the lack of social order and minimal resources
may make triage impossible.

Whether the choice of a triage system is justifiable depends on
an evaluation of the specific system itself, its underlying values
and principles, and the setting in which it is applied.

Physician Response to Risky Situations

Over the millennia, personal values have dictated whether a physi-
cian would remain with his or her patients during extreme or
catastrophic circumstances. Physicians, even legends of medicine
such as Galen, often fled to save their own lives. In the era of
modern epidemics of unknown virulence and etiology, it remains
a personal moral decision, especially for emergency clinicians who
are on the frontline of these medical assaults.
How will physicians respond when a catastrophe involving personal risk strikes? The moral backbone of medical professionals may be tested as health care providers weigh multiple factors to determine whether to stay and carry out their professional roles or to step back and decrease their personal risk.

With incomplete information, providers may make decisions on the basis of heated emotions and panic rather than an accurate perception of risk. The decision to stay or to leave will ultimately depend on the individual practitioner’s risk assessment and value system. Professional ethical statements about expected conduct establish important professional standards and norms, but each practitioner will interpret and apply them on the basis of his or her own situation and values. Recent historical precedent suggests that many physicians and other health care providers will dutifully care for the sick and needy, even at great risk to themselves. Although some emergency clinicians have worked in dangerous situations, most have not; nothing in day-to-day emergency medicine practice prepares emergency clinicians for the great opportunities and challenges that accompany a pandemic. Emergency clinicians can, however, reflect on their professional and personal responsibilities in crisis situations, and public and private institutions can create plans for effective communication and care when a disaster strikes. If this can be achieved before the next pandemic or disaster that includes personal risk to clinicians, emergency clinicians—who are inevitably among those at highest risk—can be encouraged to “stay and fight.”

“Proactive Ethics”: How Can Emergency Clinicians Change the Rules?

In every medical system, practitioners find that they repeatedly face identical ethical dilemmas. The normal outcome is an incomplete and often unsatisfactory decision made by administrators, lawyers, bioethics committees, or others. “Proactive ethics” involves changing the rules under which we operate. Easier done in some settings than in others, the process requires that all “stakeholders,” those with a vested interest in an equitable solution, first come to the table and reach a compromise. Such groups often will include physicians, nurses, EMS personnel, lawyers, religious authorities, and representatives of affected groups (eg, an organization of elders in the case of issues involving the aged). Armed with this agreement or even sample legislation that they can present to politicians, it becomes easier to change laws or administrative rules to address recurrent ethical dilemmas. One such process led to a landmark out-of-hospital advance directive law, which markedly lessened unwanted EMS resuscitation attempts. It also led to an extensive statutory surrogate list and a simplified set of advance directives. Subsequently, physicians also spearheaded the similar, but less effective Physician Orders for Life-Sustaining Treatment. Proactive ethics lies in the role of public policy—an arena in which emergency clinicians are well suited to play a pivotal role.

A Global Perspective

Emergency clinicians ever more frequently respond to acute and chronic “humanitarian catastrophes,” those conflicts and calamities generating both widespread human suffering and destructive events. While struggling to provide care in these difficult situations and sometimes to do simultaneous research, health care workers must also apply standard bioethical concepts with sensitivity to local mores.

Among the bioethical principles that directly apply to this work is that the humanitarian imperative comes first, meaning that action should be taken to prevent or alleviate human suffering arising out of disaster or conflict, and that nothing should override this principle. In addition, assistance is given regardless of the race, creed, or nationality of the recipients and without adverse distinction of any kind, with priorities based on need alone. This includes neither using offers of help to further government policy nor promoting political or religious views. Finally, physicians should be accountable, not only to the organizations with whom they work, but also to the local populations whom they are there to help.

**KEY CONCEPTS**

- Bioethics is a method of using values and moral principles to come to defendable decisions for ethical dilemmas.
- Ethical dilemmas arise from conflicts between multiple good options or multiple bad options, not between good and bad choices.
- Individual rights come from another’s duty to act.
- Values come from a variety of sources: community, culture, religion, and family.
- The values driving medical decisions should be the patient’s values.
- Basic ethical principles include autonomy, beneficence, nonmaleficence, justice, and confidentiality.
- In emergency medicine, caregiver safety is an important value.

**REFERENCES**

CHAPTER e10: QUESTIONS & ANSWERS

e10.1. “Confidentiality” is all of the following except:
A. Describes the patient’s right to sufficient physical and auditory isolation so that they cannot be seen or heard by others during interactions with medical personnel.
B. Imposes a duty on health care workers.
C. May conflict with the law, especially public health statutes.
D. Presumes that what the patient tells the physician will not be revealed to any other person or institution without the patient’s permission.

Answer: A. While isolation of patients for confidentiality is a good goal the limited space and hectic nature of an ED would sometimes prevent timely and quality care.

e10.2. Which of the following can emergency clinicians always rely on for appropriate guidance when faced with ethical dilemmas?
A. State laws and medical board policies
B. The American College of Emergency Physicians’ (ACEP) Code of Ethics
C. The Hippocratic Oath
D. None of the above.

Answer: D. All of these examples are great for guidance on ethical dilemmas none of them can “always” have guidance for every situation that can occur.

e10.3. To have adequate decision-making capacity in any particular circumstance, a person must understand all of the following except:
A. The available options
B. The consequences of acting on those options
C. The costs and benefits of consequences in relation to a relatively stable framework of personal values and priorities
D. The court’s decision about their competency

Answer: D. To be deemed competent an individual must understand A, B, and C. Answer D is a legal issue and is not required for competency.

e10.4. Withholding treatment in the emergency department (ED):
A. Legally differs from withdrawing treatment.
B. Morally differs from withdrawing treatment.
C. Requires clinical information that is often unavailable immediately.
D. Should never be done.

Answer: C. In an emergency not all relevant information is available at the time important decisions must be made.

e10.5. When using the “rapid approach to ethical problems in the emergency department (ED)” to decide on a course of action:
A. Always consult with the Bioethics Committee/Consultant before acting.
B. Assume that each ethical problem in the ED requires a unique solution.
C. Test your chosen action against your religious values.
D. When practicable and safe for the patient, buy time to consult on possible options.

Answer: D. Ethical problems can often take some time to work out, but a rapid approach rarely has enough time for a formal ethics consult. Buying some time so a reasonable solution can be derived is often the best that can be done.
## PRINCIPLES

### SPECIFIC ISSUES—EMERGENCY MEDICAL TREATMENT AND ACTIVE LABOR ACT

- Medical Screening Examination
- National Emergencies or Disasters
- Sexual Assault Cases
- Police-Requested Blood Alcohol Tests
- Health Care Providers Qualified to Perform the Medical Screening Examination
- Ancillary Services as Part of the Medical Screening Examination
- Policies, Procedures, and Practice Guidelines
- Registration Process, Collections or Insurance Information, and Authorization
- Documentation
- Stabilization Requirements
- Disposition Issues Under Emergency Medical Treatment and Active Labor Act

### CONSENT FOR MEDICAL CARE

- Informed Consent
- Federal Versus State Laws
- Reasonable Person Versus Professional Disclosure Standard
- Emergency Clinician Role in the Consent Process
- Implied Consent in Emergency Situations
- Minors
- Incompetent or Incapacitated Adults
- Other Special Populations of Patients

### REFUSAL OF MEDICAL CARE

- Informed Refusal
- Federal Rules
- Jehovah’s Witnesses

### REPORTING REQUIREMENTS

CHAPTER e11  Emergency Medical Treatment and Active Labor Act and Medicolegal Issues

Key Concepts

- Emergency Medical Treatment and Active Labor Act (EMTALA) governs virtually every aspect of hospital-based emergency services. Hospitals and emergency clinicians need to address the following issues to ensure compliance with the law:
  - Adopt (and enforce) a hospital-wide EMTALA policy, as well as emergency department (ED)–specific policies.
  - Educate all appropriate hospital staff and medical staff.
  - Define the hospital’s standard ED medical screening examination (MSE) process, including identifying “dedicated emergency departments” and designated “qualified medical personnel” to perform the MSE, as defined by the government.
  - Establish the hospital’s patient stabilization procedures and documentation.
  - Do not delay access to the MSE, stabilizing care, on-call physicians, or transfer on account of or to inquire about the patient’s insurance status (EMTALA’s “no-delay” provision).
  - Address the ED/outpatient registration procedures and payment collection systems.
  - Implement processes and procedures regarding patient refusal of the MSE, stabilizing treatment, or transfer.
  - Implement an effective ED physician on-call system, with written duties and responsibilities.
  - Create a uniform system and “transfer packet” for transferring patients out of the hospital.
  - Create a system for accepting or rejecting patient transfers from other facilities.
  - Institute appropriate documentation requirements for ED medical records, a “central log” for patients presenting to the hospital, transfers, and on-call lists.
  - Post required “signs” in areas used for MSEs, including the ED, Labor and Delivery, and psychiatric intake centers.
  - Monitor and quality assurance review the hospital’s EMTALA compliance.
  - Draft a policy and procedure to report suspected EMTALA violations to Centers for Medicare and Medicaid Services (CMS).
  - Review the potential application of EMTALA to the hospital’s outlying facilities, such as Urgent Care Centers, or Ambulance/Helicopter EMS Services.
  - Review disaster plans and public health emergency responses for EMTALA issues.
  - Draft and use legally-approved EMTALA forms to achieve/document compliance.
  - Whenever emergency clinicians are in doubt about the legality of a situation, they should “do what you believe to be in the patient’s best interest and worry about the legal consequences later.”
  - Consent for minors in the ED is really a non-issue. Consent is a creature of state law; EMTALA pre-empts state law, and it requires the ED to provide a MSE and stabilizing treatment to all minors presenting to the ED.
  - Emergency clinicians should be reticent to allow patients to leave the ED against medical advice. The capacity to make reasonable medical decisions can easily be affected by alcohol, drugs, pain, or any number of medical conditions. “When in doubt, don’t let ‘em out” should be the guiding principle. The courts (and public opinion) will bend over backward to protect clinicians who act in the best interests of the health and safety of their patients.
Emergency Medical Treatment and Active Labor Act and Medicolegal Issues

Robert A. Bitterman

CHAPTER e11

PRINCIPLES

Federal and state laws tightly control the practice of emergency medicine. The magnitude and complexity of the governing legal authority plus the significant penalties for noncompliance, such as criminal sanctions, civil lawsuits, civil monetary penalties, and exclusion from participation in Medicare and Medicaid, dictate that emergency clinicians acquire functional knowledge of these laws.

Federal law—the Emergency Medical Treatment and Active Labor Act (EMTALA), also known as the antidumping statute—governs how emergency clinicians must triage, register, examine, provide evaluation, treat or stabilize, discharge or transfer, use hospital resources, and involve medical staff expertise when caring for patients presenting to the ED.2-4 State laws further control the practice of emergency medicine through such issues as consent, reporting requirements, confidentiality requirements, forensic and police matters, civil commitments, and emergency medical service (EMS) statutes.

SPECIFIC ISSUES—EMERGENCY MEDICAL TREATMENT AND ACTIVE LABOR ACT

EMTALA originally was enacted to prevent private hospitals from refusing to treat indigent patients with medical emergencies or transferring (“dumping”) them in an unstable condition to public hospitals. Subsequent amendments to the law, government regulations, and court decisions greatly expanded the reach of EMTALA, such that the law now sets national standards for the provision of emergency services.2-4 Today, emergency clinicians must have a solid understanding of EMTALA’s statutory requirements and how the regulatory agencies and the courts interpret the three main aspects of the law: screening, stabilizing, and discharging or transferring ED patients.

Medical Screening Examination

Any person who comes to an ED requesting examination or treatment for a medical condition must be provided with an appropriate medical screening examination (MSE).5 The purpose of the MSE is to determine whether the patient has an emergency medical condition (EMC).6,7

Emergency Medical Condition

EMTALA defines an EMC as “acute symptoms of sufficient severity (including severe pain) such that the absence of immediate medical attention could reasonably be expected to result in (1) placing the health of the individual (or, with respect to a pregnant woman, the health of the person or her unborn child) in serious jeopardy, (2) serious impairment to bodily functions, or (3) serious dysfunction of any bodily organ or part.”8 In the case of a pregnant woman who is having contractions, an EMC is defined as one in which “there is inadequate time to effect a safe transfer to another hospital before delivery, or that transfer may pose a threat to the health or safety of the woman or the unborn child.”9

If the MSE does not reveal an EMC, further care of that patient is not controlled by EMTALA, so the law’s provisions governing stabilizing treatment, transfer of the patient, or involvement of on-call physicians cease to apply.10 This interpretation emphasizes the critical importance of documenting the presence or absence of an EMC during a patient’s initial ED evaluation. A checkbox to indicate such should be on every ED medical record.

Screening Each Individual Patient

Everyone who presents to the ED requesting care must be screened. Whether the patient is indigent, a member of a managed care plan, or covered by Medicare, Medicaid, or private insurance is irrelevant; the hospital must provide everyone who presents for care with an MSE.11 This includes all populations of patients, such as illegal aliens, minors, and private patients of the hospital’s medical staff, but excludes persons who are already patients of the hospital, such as inpatients or outpatients undergoing a scheduled procedure at the hospital who are brought to the ED for emergency care.12,14 The screening of minors is discussed later in the Consent for Medical Care section.

Request for Examination or Treatment of a Medical Condition

Mere presence in the ED or on hospital property is not sufficient to trigger the hospital’s duty to provide an MSE; a request for examination or treatment of a medical condition also is necessary. The request can be made by anyone on behalf of the patient, including EMS personnel, a police officer, or a babysitter; the request does not have to come from the patient, a family member, or a legal guardian.12

Also, if a person is unable to speak to request care, that person’s behavior may constitute a request if the hospital’s personnel are aware of the behavior and a prudent layperson would believe that the behavior indicated a need for examination or treatment.2

“Comes to the Emergency Department”

The Centers for Medicare and Medicaid Services (CMS) deems anyone on hospital property to have “come to the emergency department.”16,17 According to CMS, “hospital property” consists of the entire main hospital campus, including parking lots, sidewalks, and driveways, and any ambulance owned and operated by the hospital, even if the ambulance is not on hospital grounds.18,19 CMS then divides hospital property into “dedicated emergency departments” and all other property that is not a dedicated ED.
A dedicated ED is defined as any department or facility of the hospital, whether on or off campus, that is licensed by the state as an ED; is held out to the public as a place that provides care for persons with EMCs on an unscheduled basis; or actually does provide care for persons with EMCs a certain percentage of the time. Units qualifying as dedicated EDs include typical hospital EDs, labor and delivery units, and psychiatric intake centers. Urgent care centers generally fail to meet CMS’s regulatory definition of a dedicated ED and therefore do not have to comply with EMTALA. However, urgent care centers legally structured as a hospital “department of the provider” need to review the EMTALA regulations to determine whether the EMTALA applies.7

CMS specifically exempts a number of on-campus areas from compliance with EMTALA—in general, those areas that typically do not provide emergency care, such as physicians’ offices, skilled nursing facilities, other entities that participate separately under Medicare, and other nonmedical facilities on campus.8 CMS also exempts application of the law to off-campus facilities and other “departments of a provider” that were never intended or structured to manage EMCs, such as dialysis centers, rehabilitation units, laboratories and radiology centers, and primary care clinics. However, these facilities must have written policies and procedures for appraisal of emergencies and arrangement of transfer when it is appropriate.12,13

Presentations to the hospital’s dedicated ED require only a request for examination or treatment of a medical condition; it is not required that the presentation be for a medical condition that constitutes a true emergency to trigger EMTALA’s screening duty. Presentations to hospital property other than to the dedicated ED do, however, require the request to be for an EMC before EMTALA applies.3,14

“Parking” of Patients Brought by Emergency Medical Services to the Emergency Department

Some overcrowded hospitals ignore ambulance patients, leaving EMS to care for them until the hospital “accepts” the patient, a practice termed EMS “parking.” These hospitals erroneously believe that unless they accept responsibility for the patient, they have no EMTALA duty to provide care or to accommodate that patient. CMS deems a hospital’s EMTALA obligation to begin the moment the patient “comes to the ED” and a request is made on behalf of the patient for examination or treatment of a medical condition, not when the hospital “accepts” the patient.14 The practice of “parking” EMS patients also may violate other Medicare regulations, which require hospitals to “meet the emergency needs of patients in accordance with acceptable standards of practice.”15

Under certain circumstances, such as an influx of multiple trauma victims, it is reasonable for the hospital to ask the EMS provider to stay with the patient until such time as ED staff becomes available to care for that person. However, CMS requires that “even if a hospital cannot immediately provide an MSE, it must still triage the individual’s condition immediately upon arrival to ensure that an emergent intervention is not required and that the EMS provider staff can appropriately monitor the individual’s condition.”16

National Emergencies or Disasters

Under certain circumstances, the Secretary of Health and Human Services can exempt hospitals from EMTALA during times of national or local disasters or terrorist acts, bioterrorist events, or pandemic infectious disease.17,18

EMTALA still applies to individuals potentially exposed to Ebola virus, or other highly contagious diseases, who present to the hospital’s ED (Box e11.1).
designation is “physicians—credentialed members of the medical staff,” and “physician assistants (PAs) or nurse practitioners (NPs) under the direction of an emergency clinician.” CMS specifies that the hospital cannot allow the medical director of its ED to designate who is qualified to perform screenings on behalf of the hospital.

Triage by a nurse does not constitute an MSE, even for “obvious” nonemergent conditions. Neither CMS nor the courts accept triage as adequate to determine whether an EMC exists.

**Ancillary Services as Part of the Medical Screening Examination**

The law requires hospitals to provide the screening examination “within the capabilities of the hospital's emergency department, including ancillary services routinely available to the ED.” According to CMS, this means that the scope of an MSE may “range from a simple process involving only a brief history and physical examination to a complex process that also involves performing ancillary studies and procedures, such as (but not limited to) lumbar punctures, clinical laboratory tests, computed tomography (CT) scans, and/or diagnostic tests and procedures.”

Because the stated purpose of the MSE is to determine whether an EMC exists, CMS and the federal courts hold that the hospital must conduct whatever examination is necessary to make that determination. It may take only a visual glance to rule out an EMC in a patient with a rash. However, if it takes a complete neurologic examination, CT scan, and lumbar puncture to decide whether a headache patient has a subarachnoid hemorrhage, then those procedures are considered part of the MSE.

Thus, if the ED usually has ultrasonography, CT, ventilation-perfusion scans, and similar tests available, it must use those resources if necessary to determine whether the patient has an EMC. However, the hospital is obligated to use only the resources ordinarily available to its ED. Neither the statute nor the regulations mandate that hospitals expand resources or offer additional services to ED patients.

CMS views the ancillary services available to the ED as including the services of on-call physicians if their expertise is required to decide whether the patient has an EMC. If the emergency clinician cannot determine whether a patient has an EMC, the clinician must use the on-call physician services to help make that determination. For example, if it takes an on-call surgeon to decide whether a patient has an “acute abdomen,” the surgical evaluation becomes an integral part of the hospital's MSE.

**Policies, Procedures, and Practice Guidelines**

An appropriate MSE has two components: (1) the examination must be “reasonably calculated to identify critical medical conditions,” and (2) the “exact same level of screening must be uniformly provided to all patients who present with substantially similar complaints.” In other words, a hospital satisfies the requirements of EMTALA if it conducts standard screening procedures, uniformly, for all patients with similar complaints and circumstances.

Each hospital determines its own standard screening policies and procedures. By necessity, each hospital's standard will be individualized because each hospital ED has its own capabilities and different ancillary services available. Once a hospital defines its standard screening process, however, it must apply that process uniformly to all patients presenting with similar complaints, and material departure from its standard screening procedure constitutes inappropriate screening under EMTALA. Because motive is not a relevant issue in the federal courts (except the Sixth Circuit Court) or during CMS investigations, liability may result from any material deviation of the hospital’s screening process, regardless of the hospital’s motive and regardless of the reason for the deviation. For example, a Florida hospital's screening policy stated that triage would be conducted within 3 minutes after a patient's arrival at the ED. In one instance, a patient was not triaged until 45 minutes after arrival; this delay constituted a violation of the law because the hospital did not follow its own policy. Once hospitals define their own standard screening process, they will be held to that standard, by both plaintiffs and the government enforcers. Investigators and plaintiff attorneys will subpoena and closely examine the hospital's policies and procedures, medical staff bylaws, ED rules and regulations, practice guidelines, and other written information on the screening process. They will compare the written process to what actually transpired. These hospital documents must be drafted very carefully to avoid unintended liability.

**Registration Process, Collections or Insurance Information, and Authorization**

CMS does allow hospitals to conduct reasonable registration procedures in the ED, including collection of insurance data at the time of registration, as long as the process does not delay the MSE. A reasonable registration process may obtain demographic data and the name of the patient’s physician and determine whether the patient is insured and the type of insurance. During the registration process, the patient can sign the hospital’s usual “informed consent to be examined” form and a routine form that holds the patient financially accountable for any charges not covered by the patient’s insurance carrier.

The key is to create parallel tracks for medical and financial issues and to ensure that the financial track never interferes with the medical care in any way. “Bedside registration” is probably necessary under the existing regulatory scheme to avoid “no-delay” violations because CMS would consider any delay in access to the MSE due to diversion to the registration area to be against the law. Waiting for examination and treatment because the ED is overwhelmed is not a violation, but waiting for examination because the registration clerks are collecting insurance information probably is a violation.

CMS warns hospitals not to coerce patients into leaving before they receive their federally guaranteed MSE, stating “reasonable registration processes may not unduly discourage individuals from remaining for further evaluation.” Moreover, since enactment of the Affordable Care Act, CMS now considers collection of co-payments, down payments, advanced beneficiary notifications, or signatures on managed care financial forms to constitute such “economic coercion” and therefore prohibited.

Hospitals also should ensure that staff behavior does not create a hostile environment or constructive denial of the MSE.

Furthermore, hospitals should never delay a patient’s MSE to obtain prior authorization from a managed care organization (MCO). CMS explicitly bans prior authorization for managed care plans before completion of the MSE and commencement of stabilizing treatment. Hospitals may obtain authorization for payment from insurance entities only “concurrently” with stabilization of the patient. Hospitals are legally obligated to provide the MSE, and they will be held to that standard regardless of the financial pressures placed on them by MCOs.

Regardless of managed care status, “very important person (VIP)” status, private patient status, or any other classification, all patients should be processed in the same manner. In addition, the triage team, emergency clinician and nursing staff, and all clinical personnel should not know the patient’s insurance status throughout the initial screening and stabilizing treatment. This removes insurance status as an issue should the government later claim that the staff was motivated in some way or treated the patient disparately on the basis of financial class. It is easier to
prove that actions were not predicated on the patient’s financial status when the staff lacked knowledge of that status than to prove that the actions were medically appropriate despite knowledge that the patient had no insurance.

After the MSE and initiation of stabilizing treatment, insurance status and ability to pay can be considered in determining the patient’s future care, such as hospital admission, transfer, or discharge and follow-up.

**Documentation**

Compliance with EMTALA’s technicalities requires proper documentation. Furthermore, clinical outcomes are irrelevant under government enforcement, and compliance is not presumed; hospitals must prove compliance through documentation.

**Central Log**

Hospitals must maintain a central log of all patients presenting to the ED requesting examination or treatment. The log must contain the name and disposition of the patient, including whether the patient refused treatment, whether the hospital refused to provide an MSE or treatment, and whether the patient was treated and stabilized, admitted, transferred, or discharged. The purpose of the log is to permit CMS and state surveyors to select and review individual records to investigate whether the hospital is in compliance with the law. The log must include all persons presenting to the hospital’s dedicated EDs, whether on or off campus. These areas include the typical ED, ambulatory care or fast-track areas contained within the ED, freestanding emergency centers, labor and delivery suites, and psychiatric intake centers. The logs are not required to be collated into a single document but must be retrievable at CMS’s request.

**Medical Record**

All areas of the hospital used to conduct the MSE must create a medical record for the patient and keep a log of those presenting for examination and treatment. If members of the hospital medical staff see their patients in the ED, on either a scheduled or an unscheduled basis, the hospital must create a medical record and require the physician to document the care provided in that record. The physician’s private office records documenting care provided at the hospital are insufficient.

Most important, the emergency clinician should document whether an EMC was determined to exist for every patient seen in the ED, even if the initial chief complaint is seemingly trivial. The legal purpose of the required MSE is to determine if an EMC is present. To facilitate documentation, ED charts should include two checkboxes: one labeled “EMTALA EMC present” and the other “EMTALA EMC absent.” The person performing the MSE should check the appropriate box for each patient, and completion of this documentation should be a prime part of the ED’s quality improvement monitoring program.

**Stabilization Requirements**

Once the hospital determines that an individual has an EMC, EMTALA requires the hospital either to stabilize the EMC or, if it lacks the capability to stabilize the patient, to transfer the patient to another medical facility that can provide the necessary treatment. A sample form for use in documenting such transfers and patient consent to transfer is shown in Figure e11.1.

When and if the patient is “stabilized” has significant ramifications for hospitals and physicians, because once patients are stabilized, EMTALA no longer applies. After stabilization, hospitals are free to refuse to provide further treatment or to transfer stabilized patients for purely financial reasons. On-call clinicians can refuse to treat or to admit stable patients or insist that stable patients be transferred owing to their lack of or type of insurance. An MCO can refuse further payment to the hospital and request that the stabilized patient be transferred to one of its contracting facilities.

However, other federal, state, or local standards may govern further treatment or transfer of ED patients. For example, state laws often prohibit hospitals from transferring patients for any reason except that they are incapable of handling the patient’s medical problem.

Two elements must be present to trigger EMTALA’s stabilization requirement: (1) the patient must have an EMC, as defined by law, and (2) the hospital must determine that an EMC exists. That an EMC exists is not sufficient to invoke the duty to stabilize; the hospital also must have actual knowledge that the EMC is present. Actual knowledge is a legal term that means the examining emergency clinician subjectively determined that an EMC existed. It is not the commonly understood objective standard used in malpractice cases, wherein liability is predicated on whether the physician knew or reasonably should have known that the patient had an emergency condition. Whether the physician’s judgment was negligent, or even grossly negligent, is irrelevant under EMTALA. The subjective perception of the examining emergency clinician controls whether EMTALA’s stabilization requirement is triggered.

The appellate courts have uniformly held that if an EMC is not detected, the hospital has no stabilization duty and cannot be charged with failure to stabilize the patient’s condition. Furthermore, consideration or suspicion that an EMC may exist does not rise to the level of actual knowledge. If the hospital fails to detect an EMC through its standard screening procedures, the patient has only a state malpractice claim of “failure to diagnose” and not a federal cause of action for “failure to stabilize” the emergency condition. Once the physician or hospital does diagnose an EMC, however, the courts will allow a failure-to-stabilize claim to be brought in federal or state court under EMTALA.

This aspect of EMTALA is distinctly different from ordinary malpractice. Documentation in the medical record of “no EMC present” eliminates all further civil liability under EMTALA; understanding and use of this distinction should be part of every ED’s risk management program.

The screening section of EMTALA mandates the hospital to provide only those services within the capability of the ED, including ancillary services routinely available to that department. The stabilization section, however, requires the level of services within the capabilities of staff and facilities available at the hospital. The capabilities of the hospital staff include whatever intensity of care the personnel of the hospital can provide within the training and scope of their professional licenses and hospital privileges. To ensure that hospitals can stabilize patients, Congress mandated that Medicare-participating hospitals maintain a list of on-call physicians available to provide treatment necessary to stabilize a patient with an EMC.

Thus, whenever the ED determines that a patient has an EMC, the hospital must use the full capabilities of its staff, facilities, and on-call physicians to stabilize the patient. If the hospital is unable to stabilize the patient, a physician must certify that a transfer is medically indicated and arrange an “appropriate” transfer to a higher level facility.

The treating emergency clinician needs to decide whether a patient’s EMC is stable or unstable. If two clinicians disagree about whether the patient is stable but only one of the clinicians is at the bedside caring for the patient, the on-site clinician should...
Emergency Medical Condition (EMC) Identified: (Mark appropriate box(s), then go to Section II) [Dr. Bitterman - 2015]

I. MEDICAL CONDITION: Diagnosis

- No Emergency Medical Condition Identified: This patient has been examined and an EMC has not been identified.
- Patient Stable - The patient has been examined and any medical condition stabilized such that, within reasonable clinical confidence, no material deterioration of this patient’s condition is likely to result from or occur during transfer.
- Patient Unstable - The patient has been examined, an EMC has been identified and patient is not stable, but the transfer is medically indicated and in the best interest of the patient.

II. REASON FOR TRANSFER: [ ] Medically Indicated [ ] Patient Requested

- On-call physician refused or failed to respond within a reasonable period of time.
- Other ____________________________________________________

III. RISK AND BENEFIT FOR TRANSFER:

- Medical Benefits:
  - Obtain level of care/service NA at this facility.
  - Service
  - Benefits outweigh risks of transfer

- Medical Risks:
  - Deterioration of condition in route
  - Worsening of condition or death if you stay here.
  - There is always risk of traffic delay/accident resulting in condition deterioration.

IV. Mode/Support/Treatment During Transfer As Determined by Physician - (Complete Applicable Items):

- Mode of transportation for transfer: [ ] BLS [ ] ALS [ ] Helicopter [ ] Neonatal Unit [ ] Private Car [ ] Other

- Support/Treatment during transfer:
  - Cardiac Monitor
  - Oxygen - (Lites): __________
  - Pulse Oximeter
  - IV Pump
  - IV Fluid: __________ Rate: __________
  - Restraints - Type: __________ Other: __________ None

- Radio on-line medical direction control (if necessary): [ ] Transfer Hospital [ ] Destination Hospital [ ] Other

V. Receiving Facility and Individual: ____________________________________________________________________________

- The receiving facility has the capability for the treatment of this patient (including adequate equipment and medical personnel) and has agreed to accept the transfer and provide appropriate medical treatment.

- The receiving facility has the capability for the treatment of this patient (including adequate equipment and medical personnel) and has agreed to accept the transfer and provide appropriate medical treatment.

- Receiving Facility/Person accepting transfer: ___________________________________________ Time: __________________

- Receiving MD: ___________________________ Receiving Facility/Person accepting transfer: ___________________________________________ Time: __________________

- Transferring Physician Signature: ___________________________ Date/Time: __________________

- Per Dr. ___________________________ by ___________________________ RN/Qualified Medical Personnel ____________ Date/Time: __________________

VI. ACCOMPANYING DOCUMENTATION - sent via: [ ] Patient/Responsible Party [ ] Fax [ ] Transporter

- Copy of Pertinent Medical Record [ ] Lab/ EKG/ X-Ray [ ] Copy of Transfer Form [ ] Court Order

- Advanced Directive [ ] Other

- Report given (Person/title): ___________________________________________ Date/Time: __________________

- Time of Transfer: ___________ Date: ___________ Nurse Signature: ___________________________ Unit: ___________

VII. PATIENT CONSENT TO "MEDICALLY INDICATED" OR "PATIENT REQUEST" TRANSFER:

- I hereby CONSENT TO TRANSFER to another facility. I understand that it is the opinion of the physician responsible for my care that the benefits of transfer outweigh the risks of transfer. I have been informed of the risks and benefits upon which this transfer is being made.

- I hereby REQUEST TRANSFER to ___________________________, I understand and have considered the hospital’s responsibilities, the risks and benefits of transfer, and the physician’s recommendation. I make this request upon my own suggestion and not that of the hospital, physician, or anyone associated the hospital.

- The reason I request transfer is: _____________________________________________________________

- Signature of Patient: ___________________________ Responsible Person: ___________________________ Relationship: _____________

- Witness: ___________________________ Relationship: _____________

TRANSFER FORM

- Patient Name: ___________________________ Date of Birth: ___________________________

- Medical Record Number: ___________________________

The Practice of Emergency Medicine

make the decision.2 It is not appropriate for an on-call physician, a “managed care gatekeeper” physician, a physician at a receiving facility, or even the patient’s regular attending physician to disagree with the decision of the on-site physician over the phone. If one of these outside physicians wants to overrule the determination of the on-site clinician, he or she must come to the hospital and personally examine the patient.

EMTALA defines the term stabilized as follows: “no material deterioration in the condition is likely, within reasonable medical probability, to result from or occur during the transfer of the individual from a facility.”24 For a pregnant woman having contractions who has an EMC, stabilized means that delivery (including the placenta) has occurred.40

This is a legal definition of stabilization, not a medical definition. The standard of care for any patient diagnosed with an EMC will be judged by this legal definition, not by the usual medical malpractice standards. This is a national standard under federal law, not a local standard under state malpractice law.9,40

The question of “stabilization” typically arises only when the patient deteriorates during or after the transfer and experiences an adverse medical result. It is likely to appear, particularly in hindsight, that the patient was not completely stabilized before transfer. Health care providers should remember that their compliance usually will be judged by an unsympathetic jury, aided by hindsight, in the context of impairments suffered by the patient in an adverse medical outcome. Unfortunately, the court system, not the health care system, will ultimately determine when a patient with an EMC is legally “stabilized.”23

Furthermore, the U.S. Supreme Court, in the case of Roberts v Galen, ruled that a plaintiff need not show improper motive for a transfer to prevail on a failure-to-stabilize claim under EMTALA. The plaintiff merely must prove that the patient was not properly stabilized before the transfer.47

EMTALA’s requirement to provide on-call physicians no longer extends to inpatients diagnosed with an EMC.2 Other Medicare conditions of participation govern inpatient care, and hospitals certainly should implement policies and procedures to provide emergency specialty services to patients in whom an EMC develops after admission to the inpatient setting.2

Disposition Issues Under Emergency Medical Treatment and Active Labor Act

Admission

Once the emergency clinician determines that a patient needs to be hospitalized, the patient’s physician or the appropriate on-call physician should be contacted. If the admitting or on-call physician disagrees with the emergency clinician’s judgment, it is incumbent on the admitting or on-call physician to come to the ED to personally examine the patient. This fact should be mutually understood by the entire medical staff and the hospital administration and should be written into hospital policy and procedure.

CMS does not apply the law to inpatients regardless of whether they are directly admitted to the unit, directly admitted by way of the ED, or “boarded” in the ED awaiting bed placement. Even if the inpatient is brought down to the ED, the law does not apply.2,21 According to CMS, once a hospital admits the individual in good faith (ie, the admission is not a ruse to avoid liability under the law) as an inpatient for further treatment, the hospital’s obligation under EMTALA ends.31,42

An inpatient is defined as “an individual who is admitted to a hospital for bed occupancy for purposes of receiving inpatient hospital services … with the expectation that he or she will remain at least overnight.”32 It does not matter if the situation changes later and the patient can be discharged or transferred to another hospital and does not actually use the bed overnight. The key element is that the patient be formally admitted with a documented admission order. An emergency clinician’s intent to admit or a level of acuity indicating that the patient “obviously will be admitted” is not enough to satisfy the definition. Documentation is critical.2,21

CMS does not consider patients admitted to “observation” status to meet the regulatory definition of admitted patients (not admitted for purposes of receiving inpatient services), so EMTALA still applies to the care of observation patients, such as patients managed in ED chest pain or observation units.2,21 Therefore, under existing government regulations, persons who were directly admitted and sent through or held in the ED from a physician’s office, from a nursing home, or in transfer from another ED or another hospital inpatient setting are no longer covered by EMTALA, even though they have “come to the hospital’s emergency department.”

However, in 2009 the Sixth Circuit Court of Appeals in the case of Moses v Providence Hospital rejected CMS’s interpretation, giving no deference to the agency’s rulemaking authority. It overruled CMS’s regulation that EMTALA ended when the hospital admitted the patient in good faith.47 The court determined that the rule was contrary to EMTALA’s plain language, which requires a hospital to “provide … for such further medical examination and such treatment as may be required to stabilize the medical condition.”3,45 Therefore, the Sixth Circuit Court held that the hospital was required under EMTALA not just to admit the patient into an inpatient unit for further care but to actually treat him such that he was stabilized before discharge.47 Subsequently, the U.S. Supreme Court declined to review the controversial Sixth Circuit decision in Moses, so presently in the states of Michigan, Ohio, Tennessee, and Kentucky, EMTALA applies to inpatients, at least for civil litigation purposes, even if CMS will not apply that law to inpatients for regulatory purposes.3,45-48

“Discharge” or “Transfer” to Home

Because EMTALA defines any patient movement away from the hospital as a transfer, all patients discharged from an ED are legally considered to have been transferred.49 Sending a patient home after treatment in the ED who is retrospectively determined to be unstable is considered to transfer the patient, and as such, a violation of the law. This exposes the hospital to civil litigation under EMTALA for failure of its emergency clinicians to stabilize patients with known emergency conditions before discharge (“transfer”) home.47

To avoid such retrospective analyses, emergency clinicians should document that no emergency condition was found or that the patient was stable on discharge. If the patient leaves without permission, the hospital has not legally discharged the patient.47

“Discharge” or Transfer From the Emergency Department to an On-Call Physician’s Office

Because all discharges from the ED are defined as transfers under EMTALA, so too are discharges from the ED sent directly to an on-call physician’s office for acute intervention. CMS looks askance at transfer of patients away from the hospital to a physician’s office for acute procedures that could have been done in the ED or in the hospital.3,49 Ophthalmologist services may constitute an exception because although the ED may have rudimentary eye tools; ophthalmologists typically have much better equipment in their offices for examination of patients with eye complaints to determine whether an EMC is present or to treat emergency conditions. In essence, movement to the office in these cases becomes a medically indicated transfer to receive a higher level
of services than the hospital can provide. CMS accepts such movement, so long as the ED arranges a formal transfer in compliance with EMTALA, as noted later.

CMS’s view is extremely unsatisfactory, particularly to orthopedic surgeons. It is standard practice in most hospitals for the emergency clinician to splint various displaced fractures and send the patient to the on-call orthopedic surgeon’s office for reduction of the fracture and further necessary treatment. CMS believes that the orthopedic surgeon should perform the reduction and treatment at the hospital in each case because the surgeon’s office has no resources that the hospital lacks.

However, EMTALA applies only if the EMC is unstable at the time of transfer. If the ED “stabilizes” the fracture, EMTALA’s obligations end. Thus it is reasonable to send patients to the office for further treatment, so long as they meet the legal definition of “stable at the time of discharge” from the ED. The determination of whether the patient is stable for transfer to the orthopedist’s office rests solely on the judgment of the examining emergency clinician. If the patient has accompanying injuries or is too uncomfortable to be moved, or if the emergency clinician believes the injury is such that the patient should not travel, then the orthopedic surgeon should be asked to care for the patient in the ED.

Follow-Up Care

If the patient does not have an EMC or is stable at the time of discharge, EMTALA does not apply from that point forward, and the on-call physician has no legal duty under EMTALA to see the patient in the office.

The real ED follow-up issue is the level of commitment the hospital and medical staff are willing to make to the community. If the administration, the board, and the medical staff are comfortable with their decision and if they have acted in the best interests of the patients that they serve, they should have no trouble defending their actions to CMS or any other entity.

Whatever decision the hospital and physicians make about ED follow-up duties, they should explicitly define those responsibilities in the medical staff bylaws or hospital rules and regulations so that all personnel understand, prospectively, what it means to be “on call” for the ED at that hospital.

ED discharge instruction sheets also should include a fail-safe clause advising patients to return to the ED if their condition deteriorates before seeing the referral specialist or if the follow-up arrangements disintegrate for any reason. Such a statement could help the hospital avoid liability when the on-call specialist fails to implement the prescribed follow-up plan.

Transfers to Other Acute Care Hospitals

Before transferring a patient out of the ED, the emergency clinician must first determine whether the patient is stable, as defined by law. EMTALA regulates the transfer of unstable patients only; it does not apply to the transfer of stable patients. If no emergency condition is found, the patient is considered stable. The determination of whether a patient is stable must be made at the time of transfer to be valid under the law. Unstable patients can be transferred for only one of two reasons: if the transfer is medically indicated, or if the patient requests the transfer.

Patients usually are transferred out of the ED because the transferring facility lacks the capability or the resources necessary to treat the identified emergency condition. Examples of patients best served by transfer are the head-injured patient in a hospital without a neurosurgeon on staff, the pregnant woman who needs the services of a high-risk obstetric center, and the multiple-trauma patient treated initially in a rural ED who requires treatment at a level 1 trauma center.

EMTALA defines such transfers as medically indicated transfers because the purpose of each transfer is to obtain a higher level of medical care necessary to treat the patient’s condition that is not available at the transferring facility. EMTALA governs almost every aspect of medically indicated transfers, including requiring hospitals to adopt and to enforce policies to ensure compliance with federal transfer laws and mandating specific actions by the transferring and receiving hospitals (summarized in Boxes 11.2 to 11.4). Some states have enacted their own transfer laws. Most state laws parallel EMTALA, but some are even more restrictive, so emergency clinicians responsible for patient transfers should be aware of the controlling laws and regulations in their own state as well as under federal law.

Duty to Accept Appropriate Transfers From Other Hospitals

Medicare-participating hospitals that have specialized capabilities or facilities are required by EMTALA to accept appropriate transfers of patients who require such capabilities or facilities, if the hospital has the capacity to treat the patient.

The duty to accept patients in transfer is a problematic issue for many larger, tertiary care, or academic hospitals as a result of

---

**BOX e11.2**

**Recommended Procedures for the Transferring Facility**

- Stabilize the patient whenever possible.
- Complete a physician certificate of transfer, including the risks and benefits of transfer.
- Obtain the patient’s informed consent to the transfer.
- Arrange for another hospital and physician to accept the patient in transfer.
- Send appropriate data to the accepting facility (eg, medical records, test results, transfer forms).
- Arrange the transfer through qualified personnel with use of appropriate transportation equipment.
- Maintain records of all transfers for 5 years.

**BOX e11.3**

**Invalid Reasons for Refusal of an Appropriate Patient Transfer**

- Lack of insurance or out-of-network managed care plan
- Lack of citizenship
- Veteran status
- Patient’s physician not on staff
- Transferring hospital is out of network or outside hospital’s defined referral area
- “We are not an affiliated hospital.”
- “We are not a specialty hospital.”
- “We are a specialty hospital, but that’s not our specialty.”
- “We are not a ‘trauma center’”
- Transfer originating out of county or out of state (including transfer of out-of-state Medicaid patients)
- EMS bypassed closer hospital
- Another hospital refused the transfer in violation of the law
- Another hospital’s on-call physician refused to respond to its ED in violation of the law

ED, Emergency department; EMS, emergency medical service.
the on-call specialty coverage crisis in the United States. Numerous hospitals have lost full or partial on-call coverage for specialties, such as neurosurgery, orthopedic surgery, maxillofacial surgery, neurology, plastic surgery, and hand surgery, increasing the number of patient transfers.

Specialty hospitals also enticed physicians away from acute care hospitals, in part because the physicians could decrease their on-call burden. However, CMS now requires specialty hospitals to accept appropriate transfers even if the specialty hospital lacks an ED.1,2

**Who Accepts Patients on Behalf of the Hospital?** The duty to accept appropriate transfers is a hospital duty, not a physician duty, and EMTALA does not require that a physician accept the patient.1,3 Each hospital must create a formal system designating who is authorized to accept or to reject patients on its behalf. It is strongly recommended that hospitals do not use the individual physician on call for each specialty alone to accept or to reject patients in transfer. Hospitals should involve an administrative person or an emergency clinician in addition to or instead of the on-call physician to avoid inappropriate refusals. Because the duty to accept rests with the hospital, any inappropriate refusal by an uninformed or rogue on-call physician subjects the hospital to termination from Medicare, civil monetary penalties, or civil liability if the patient is harmed because of the refusal to accept the patient in transfer.

The hospital should define the resources and capacity of the institution and the times during which those resources are available. When capacity or necessary resources are not available, the hospital should in a timely manner inform the persons charged with accepting or rejecting transfers. The hospital also should educate appropriate personnel in its known referral facilities on the proper procedure to transfer patients into its system, including informing them of who is and who is not authorized to accept patients in transfer on behalf of the hospital. The hospital is required to educate its medical staff, particularly its on-call physicians and emergency clinicians, about their responsibilities under EMTALA, including the responsibility to accept patients in transfer from other facilities on behalf of the hospital.4,5

**Does a Hospital Have to Accept Transfers of Inpatients From Other Hospitals?** Current CMS-issued regulations state that no hospital has a legal duty under EMTALA to accept an inpatient in transfer from another hospital.1 Therefore, even if a requested hospital could treat an inpatient’s emergency condition that the transferring hospital is unable to treat, it may refuse the transfer for any reason, including an economic reason, and not be in violation of EMTALA.

However, the issue is certain to be litigated and decided by the courts. It is inevitable that an inpatient will develop an EMC and proceed to die or suffer severe damages because no other hospital would accept the patient in transfer due to of lack of insurance. The patient or family will sue the hospital that refused to accept the patient in transfer, claiming that the hospital had a federal duty under EMTALA to accept appropriate transfers of patients with emergency conditions if the transferring hospital could not treat the emergency. The transfer acceptance section of EMTALA was not part of the law when it was originally enacted. Congress later amended the law, calling it the “nondiscrimination” section, because tertiary and academic referral hospitals were refusing to accept patients in transfer from other hospitals, leaving the patients to die in community EDs.1,2 This issue was not specifically addressed in the Sixth Circuit opinion in the Moses case, although the court’s ruling applying EMTALA to inpatients strongly suggests that it would also apply EMTALA’s transfer acceptance section to inpatients as well as to ED patients.1,3 It thus still remains to be seen if the courts will ultimately interpret EMTALA contrary to Congress’s nondiscrimination intent for patients with life-threatening emergencies.

**When Can a Hospital Refuse to Accept a Patient in Transfer?** There are only five reasons for which a hospital can refuse a request for transfer under EMTALA. First, if the transfer is not a medically indicated transfer, a hospital can decline the transfer.1,2,4 Non–medically indicated transfers include patient-requested transfers and lateral transfers for any reason (lateral meaning that both hospitals have the same ability to handle the patient’s EMC), such as managed care transfers or family- or physician-requested transfers. Any time the sending facility can handle the patient’s EMC, a hospital requested to accept the patient in transfer can lawfully decline.

Second, if the hospital does not have the capacity, as defined by CMS, to accept the patient in transfer, it may and generally should refuse the transfer.1,2,4,5

Third, if the transferring hospital is located outside the boundaries of the United States, the hospital has no legal obligation under EMTALA to accept the transfer.1 No other territorial limits are imposed on the duty to accept transfers; out of county, out of state, and out of the hospital’s designated referral area all are invalid reasons to refuse patients in transfer under EMTALA. Moreover, a hospital cannot refuse to accept a transfer just because the sending hospital is “skipping over” other hospitals to send the patient its way.

Fourth, if the transfer is not “appropriate,” the hospital may refuse to accept the patient in transfer at that time.1,2 This more vague reason takes into account the patient’s condition at the time of transfer and the time, distance, and skipping over of other hospitals necessary to reach a receiving hospital. For example, a trauma patient may need intubation and a chest tube inserted before the transfer is appropriate, or traveling 100 miles with hypotension from a ruptured abdominal aneurysm may not be appropriate if closer hospitals are capable of repairing the aneurysm.

---

**Recommendations for the Facility Asked to Accept the Patient in Transfer**

- Accept all appropriate requests for transfer, regardless of whether the patient is an ED patient or an inpatient of the hospital.
- Have a formal system for accepting or rejecting transfer requests and document the reasons for any refusal to accept a patient in transfer.
- Maintain records of all transfers for 5 years.
- Report all EMTALA transfer violations to CMS.

---

CMS, Centers for Medicare and Medicaid Services; ED, emergency department; EMTALA, Emergency Medical Treatment and Active Labor Act.
Fifth, the patient has been “admitted” to the hospital as defined by CMS (except in hospitals under the jurisdiction of the federal Sixth Circuit Court of Appeals, at least with respect to civil liability, as noted earlier in this chapter).46,47,48

There are no other reasons for which a hospital may refuse a request to accept a patient in transfer from another acute care hospital under EMTALA. Furthermore, no “contingencies” are allowed to be placed on the acceptance of a transfer. The receiving hospital may not condition acceptance of the patient on the transferring hospital’s agreeing to take the patient back once the emergency condition is resolved, may not require that the transferring hospital have additional consultations completed before the emergency clinician transfers the patient, and may not require the transferring hospital to use the receiving hospital’s transport ambulance or helicopter service as a condition for accepting the patient.49

Also, refusals of appropriate transfers on the basis of the patient’s insurance status or delay of appropriate transfers until the transferring hospital obtains authorization for payment from the patient’s managed care plan are definitely illegal under EMTALA.50

Duty to Report Transfer Violations. Any time a hospital has reason to believe it may have received a patient transferred in an unstable condition from another hospital, in violation of EMTALA, it must report the transferring hospital to CMS.51 The duty to report rests with the hospital, so emergency clinicians who receive unstable patients in transfer should inform the hospital (risk management or the hospital’s legal counsel), which then can determine the appropriate action.

CONSENT FOR MEDICAL CARE

Informed Consent

The doctrine of informed consent is a fundamental principle of the American legal system.52,53,54 Emergency clinicians may not examine or treat any person without consent, and that consent must be informed. This means that the patient must be given all pertinent (“material”) information concerning the nature, risk, and alternatives of the treatment before that patient can be deemed to have effectively consented to the medical intervention.

Clinicians should endeavor to obtain informed consent yet remain cognizant of the significant limitations on and multiple exceptions to the doctrine, especially in the ED setting. Delaying treatment in an emergency to obtain informed consent is a much more serious and common medicolegal problem than failure to obtain proper informed consent.

The law of informed consent contains a great deal of uncertainty, with many gray areas. Different states have different views, either in their statutory laws (legislation) or in their common law (judge-made law or precedent), on the meaning of “informed consent” in the care of the ED patient. Most cases are unique and depend on the specific circumstances.

Emergency clinicians rarely have time to seek legal consultations, let alone wait for a court to render a decision concerning the legal nuances of consent issues. In these situations, it is helpful for emergency clinicians to use a when-in-doubt rule to guide their immediate actions. This rule simply states that when emergency clinicians are in doubt about the legality of a situation, “they should do what they believe to be in the patient’s best interest and worry about the legal consequences later.” Although emergency clinicians risk criminal and civil charges of false imprisonment, battery, and even negligence for failure to obtain appropriate informed consent, the courts almost universally rule in favor of physicians who act in good faith on behalf of their patients in emergency situations. Successful civil litigation regarding an issue of consent theory against an emergency clinician acting reasonably, and consistent with the appropriate standard of care, is extremely rare. An emergency clinician is much more likely to be sued for failure to treat while waiting for consent than for providing reasonable treatment without consent.

Federal Versus State Laws

Both federal laws (eg, EMTALA) and state laws govern consent.55,56 EMTALA comes into play primarily in the evaluation of minors and with patient refusal of stabilizing treatment or transfer. State consent laws vary widely and may be set by statutes or case law, or both. The concepts discussed next are generally applicable to emergency medical care, but all emergency clinicians should learn the consent laws specific to their own state.

The law presumes that an adult is mentally competent to make medical decisions and that the competent adult is entitled to sufficient information to make an informed decision concerning the physician’s proposed course of examination and treatment. Under the doctrine of informed consent, clinicians have the duty to disclose the following information to patients:

- The patient’s condition or diagnosis
- The nature and purpose of the proposed treatment, including the likelihood of success in the clinician’s practice
- Reasonable alternative measures related to the diagnosis and treatment, including the probable outcome of those alternatives
- The particular known inherent risks that are material to make an informed decision about whether to accept or to reject the proposed treatment, including the consequences of refusing that treatment

Reasonable Person Versus Professional Disclosure Standard

The states are split on the standard used to determine what should be disclosed for patients to make informed decisions, but most require the reasonable person standard of disclosure. Under this standard, a clinician is required to disclose all of the information that a reasonable person would require to make a decision under the facts and circumstances of the case. The less frequent standard, the professional disclosure standard, requires the physician to provide the same information that other physicians in the community would provide to patients in the same or similar circumstances. This is less stringent than the reasonable person standard.

Clinicians are not required to disclose every remote risk associated with a procedure or risks that are common knowledge or obvious to the patient, such as the risk of infection after wound repair.57 The law requires disclosure only of risks that are material, as judged by their seriousness or chance of occurrence. Courts define material information as information that “the physician knows or should know would be regarded as significant by a reasonable person in the patient’s position when deciding to accept or reject the recommended medical procedure.”58

Some states legally require clinicians to disclose specific risks, such as death.59 Some states statutorily require a clinician to meet both the reasonable person standard and the professional disclosure standard.60,61

Emergency Clinician Role in the Consent Process

The emergency clinician who proposes to undertake the procedure must be the one to obtain the patient’s informed consent. The duty to obtain consent cannot be delegated, so clinicians cannot ask nurses or other health care providers to obtain patients’ consent on their behalf. The emergency clinician who will care for
the patient is best qualified to discuss the treatment and its risks and benefits with the patient. Nurses as well as physicians not skilled in performing the procedure cannot obtain valid informed consent.74

The clinician should write or dictate into the patient’s medical record a summary of the discussion held with the patient and family concerning the elements of informed consent. Particular attention should be made to documentation of those material risks discussed with the patient before the patient’s consent is obtained.

Consent is a process, not a signature. A written, signed, separate consent form is not legally required under the doctrine of informed consent; however, hospitals may require emergency clinicians to complete standardized consent forms and to obtain the patient’s signature. The signed form is not a substitute for the consent process. It cannot replace the exchange of information that occurs between the physician and the patient and family, the answering of questions, and the ultimate agreement of the patient to undergo the medical or surgical intervention.76

A signed, written consent form, however, does constitute some evidence of a valid consent. In some states, a signed consent form is presumed to represent valid consent unless that presumption is rebutted by proof that the consent was obtained by fraud, deceit, or misrepresentation of material fact.75

**Implied Consent in Emergency Situations**

If an unconscious or incapacitated patient cannot express consent, the law will assume the patient consented to treatment for the emergency situation. Implied legal consent is premised on two principles: (1) duty to obtain informed consent is excused if death or irreparable harm may result if the clinician delays treatment, and (2) the law presumes that a reasonable, competent, lucid adult would consent to lifesaving treatment.79

The emergency treatment allowed is limited to the circumstances of the emergency, however, and only treatment required to resolve the emergency should be undertaken without consent. Similarly, the emergency condition must require immediate medical attention, with insufficient time to inform the patient or to seek consent from another person.

Courts differ on the definition of a “true emergency,” and whether the emergency exception applies in a given case depends on the definition accepted by the court and the application of that definition to the particular set of facts. Fortunately, the courts generally will stretch the doctrine to protect clinicians who act in good faith in caring for a patient with a perceived emergency condition.77 This is one situation in which use of the when-in-doubt rule and documentation of the clinician’s concerns will weigh greatly in the court’s determination of whether the clinician acted appropriately without obtaining informed consent. Clinicians can further protect themselves by obtaining a second opinion that a true emergency exists.

**Minors**

**Minors Accompanied by a Parent or Legal Guardian**

Parents and legal guardians have the right to consent on behalf of their minor children. However, they need to act reasonably and in the best interests of their children. If they do not, their right to consent can be abrogated by the state or the courts.78 Parents are not allowed to refuse treatment for a child with a life-threatening emergency condition. The management of children with emergency conditions whose parents refuse to give their consent to treatment is discussed later.

Either natural parent of the minor child may provide legally binding consent. If one parent agrees with a proposed treatment and the other does not, consent may be accepted from the agreeing parent. Even if separated or divorced, either parent may give consent unless one parent has been judicially granted sole legal custody of the child, in which case only the custodial parent may consent. The child’s biologic father, even if never married to the mother, also may consent for his child.

**Unaccompanied Minors**

EMTALA mandates that all persons presenting to an ED requesting care be examined to determine whether an emergency condition exists.7 Because EMTALA is federal law, it takes precedence over all state consent laws regarding the initial evaluation of a minor child. In essence, the child’s mere presence at an ED requesting examination or treatment constitutes legal consent to examination of the child to determine whether an emergency condition is present. Furthermore, the hospital should not delay this initial screening evaluation to wait for consent from a parent or legal guardian (and nurse triage does not qualify as the required medical screening, no matter how non-urgent the child’s condition appears to the nurse).

If an emergency condition is discovered through the initial screening examination, the clinician may treat the emergency under either state or federal legal theories.75,84 First, under state laws, the standard emergency exception doctrine applies. State laws allow clinicians to proceed with treatment whenever an emergency exists. Although no uniform legal definition of emergency exists among the states, state laws tend to define an emergency liberally, such as “any threat to the minor’s life or health.” The courts almost always affirm a clinician’s judgment about an emergency condition and rarely question the treatment given to a minor without parental consent.76 Preserving life, preventing permanent disability, alleviating pain and suffering, and avoiding eventual harm have been used as guidelines for emergency treatment without consent.75 Any minor presenting to the ED should be triaged and provided with an MSE to determine whether an emergency condition exists.

Under EMTALA, if an emergency condition is present, the hospital and emergency clinicians are required to provide “stabilizing treatment.”79 Federal law also gives the clinician broad discretion to decide what treatment should be performed and in what time frame it should be accomplished. The stabilization requirement includes transfer as necessary to an institution capable of handling the minor’s emergency condition. Thus, under federal law, a minor could be examined, stabilized, or transferred to another institution without consent even if being obtained from the family; in this instance, the care would be not only in the patient’s best interest but also legally mandated.5,36,49

In general, if the MSE does not reveal an emergency condition, clinicians need to obtain proper consent from the minor’s parents or legal guardian. However, state laws and the courts have applied a number of exceptions to allow minors to seek treatment on their own without parental consent. These exceptions (such as the mature minor and the emancipated minor exceptions) vary widely from state to state, and most are applied through an analysis of facts and circumstances on a case-by-case basis by the courts.79,80

In addition, most states have statutory reasons, such as sexually transmitted diseases, pregnancy, or domestic violence injuries that allow minors to seek care without the consent of their parents.41

**Incompetent or Incapacitated Adults**

If a person has been declared legally incompetent by a court, consent must be obtained from the person’s court-appointed legal guardian. In addition, people may appoint legal surrogates to make legal decisions for them should they become incompetent. State-sanctioned living wills, advance directives, and durable
medical power of attorney documents all transfer consent powers from a person who becomes incompetent to a legally appointed surrogate.68

If an incompetent adult lacks a legal guardian or an appointed surrogate, emergency clinicians typically look to the patient’s family for consent to treatment. However, consent to treatment by a family member, even the patient’s spouse, generally is not acceptable under American law unless the spouse or family member has been appointed legal guardian by a court of proper jurisdiction.82 Marriage does not confer one spouse the legal capacity to consent to medical treatment for the other spouse, even when the ill or injured spouse is incompetent.

Some states recognized this problem and enacted “family consent statutes,” which outline a hierarchy of family members who can legally provide consent when the family member becomes incapacitated.74 However, even when families have no legal standing to consent for the incompetent relative, it is wise to involve family in the medical decision-making process. Communication and concern for the family will avoid misunderstandings, surprise, and anger, which are the primary sources of litigation. Fortunately, if an emergency exists, no authorization from family is necessary to provide such reasonable care as is necessary to correct the life-threatening situation. Once the emergency is resolved, consent should be obtained from someone authorized to act on behalf of the incompetent patient. If there is no appointed legal guardian or surrogate and no state statute on family consent, the emergency clinician should seek consent authorization from the courts. The courts may appoint a guardian at that time, generally a family member, or after judicial review of the issues, the court itself may grant consent on behalf of the incapacitated person.

Other Special Populations of Patients

Prisoners

Competent prisoners generally do not surrender the right to consent by virtue of being incarcerated. However, a state or court may compel treatment on the basis of interests perceived as paramount to the prisoner’s interests.13

Alcohol-Intoxicated Patients

Alcohol intoxication itself may not render a patient incompetent to give informed consent.84 The emergency clinician should evaluate each situation individually to determine whether the patient is incapacitated by alcohol to the extent that he or she is no longer able to understand the proposed treatment, risks and benefits, and rational alternatives. In essence, the general rules for determination of whether a patient is competent to make informed decisions cannot be disregarded just because the person is intoxicated with alcohol. However, the when-in-doubt rule is particularly applicable in these cases because alcohol intoxication often is associated with occult serious illness or injury.

Alcohol intoxication, especially if it is documented by a measured blood alcohol concentration (BAC), is strongly suggestive to courts and juries of impaired mental status, even though health care workers recognize that many alcoholics are entirely rational and competent at fairly high BACs. Conversely, low BACs do not guarantee competence because other processes (eg, hypoglycemia, blood loss, impairment from other illicit substances) may cause the patient to be incompetent. Thus the patient’s clinical capacity is more important than the specific level of alcohol in determining competence.

One advantage of obtaining a BAC is that some states allow blood samples drawn solely for medical purposes to be subpoenaed later by the prosecutor for use against the driver in a driving-while-intoxicated prosecution or other criminal charges.87

The state “legal limit” of intoxication is not a measure of a patient’s competence. The legal level for driving has little if anything to do with the capacity to make informed medical decisions. However, this distinction is sometimes difficult for judges and juries to understand, and the emergency clinician can actually use the blood level to support a judgment that the patient was not competent to make informed decisions in a particular instance. At other times, it is better not to have a “number” so that the only relevant criterion for determination of the patient’s competence is the clinician’s judgment.

Patients Given Pain Medications

As with alcohol intoxication, the mere fact that a patient has been given narcotic analgesia does not render that patient incapable of consenting to invasive diagnostic procedures or surgery. Plaintiff attorneys can always argue “the patient was too snowed with drugs to give consent;” on the other hand, they can equally argue that the patient was “in too much pain to consent and would have agreed to anything to stop the pain.” Accordingly, when consent is sought from a patient who has received pain medication, the patient’s ability to understand the ramifications pertaining to the procedure should be assessed and taken into consideration, involving the family in the process if possible. The emergency clinician should document that the patient’s pre-medicated state was considered in judging the patient’s competence to make an informed decision.

REFUSAL OF MEDICAL CARE

Informed Refusal

The corollary to a patient’s right to give informed consent is the patient’s right to refuse medical care, even if such refusal results in death. The U.S. Supreme Court holds that a competent adult has a constitutionally protected right to refuse medical care.86 However, that right is not absolute. Under particular circumstances, courts will consider countervailing compelling state interests, such as preventing suicide, preserving life, and protecting innocent third parties.

Physicians who honor a competent patient’s decision to refuse treatment are not liable for any resulting bad outcome. In fact, emergency clinicians are more likely to be successfully sued for treating patients over their objections or without their consent, even when the treatment is lifesaving.

When a competent adult refuses indicated medical intervention, it often is because of fear, anger, misunderstanding, or some other failure in communication in the clinician/patient relationship. Before allowing a patient to refuse care, the emergency clinician should try to determine and resolve the underlying reasons behind the patient’s refusal.

The attending physician must always be involved when a patient refuses medical care or expresses the intent to leave against medical advice.

As with consent, refusal of medical care is a process, not a signature. It must be an informed refusal; merely having the patient sign an “informed consent to refuse examination, treatment, or transfer” form or an “against medical advice” form is not sufficient. There are four essential components of the refusal process: determining competence; ensuring an informed decision, involving others, and documenting appropriately.

Determining Competence

The emergency clinician must determine that the patient is competent to make decisions. Normal findings on the mental status
Examination without evidence of diminished mental capacity from closed head injury, severe pain, hypoxia, hypotension, alcohol intoxication, mental retardation, or mind-altering substances constitute good evidence of competency. Noting the patient’s rationale for refusing care, even if it is not reasonable, provides additional evidence of competency.74

Ensuring an Informed Decision

To be legally binding, a decision to refuse a test or treatment or to sign out against medical advice must be an informed decision. The emergency clinician should explain the severity of the patient’s condition, the potential complications, and the alternative treatments available. The emergency clinician should use terms that the patient can understand and provide the patient an opportunity to ask questions. The patient should understand that the risks of refusing care include the possibility of permanent disability and death. Ideally, a witness should be present when the clinician informs the patient and any family members.

Involving Others

The patient’s family, friends, and personal physician should be involved whenever possible. These persons should hear the same message as that conveyed to the patient, because they may be able to persuade the patient to accept the recommended therapy. If the patient expressly forbids the emergency clinician to speak with others, as is the patient’s legal right, this should be explained to them and documented in the medical record.

Documenting Appropriately

Appropriate documentation of the refusal process is necessary to protect the physician and hospital from inappropriate litigation.90 The patient should be asked to sign the refusal form.2,49 Figure e11.2 shows a sample leaving against medical advice form.

If the patient refuses to sign the form, that fact should be documented and the form signed by a hospital representative who witnessed the patient’s refusal. The medical record should reflect the patient’s mental status examination findings and competency to make informed decisions, the risks and benefits of recommended treatments, the available alternatives, and the participating family or friends. Documentation of the patient’s rationale for refusing treatment, that the patient was treated to the extent allowed by the patient, and that the patient was invited to return for care at any time offers added protection.74,90

Federal Rules

EMTALA requires hospitals to take and to document specific actions when patients refuse medical screening, treatment and stabilization, or transfer. The government and the federal courts presume that the patient requested emergency care and place the burden of proof on the hospital to demonstrate that the patient voluntarily refused care.2,49,97

There are essentially two scenarios in which patients leave the ED after refusing examination or treatment. First, some patients simply pick up and leave, without the knowledge of anyone affiliated with the hospital. If the patient’s departure is witnessed, the patient does not respond to requests to return for the examination or to discuss the issues with the hospital staff. These patients are generally referred to as those who “leave without being seen” (LWBS) or “leave before examination.” In the second scenario, the hospital personnel are aware that the patient is about to leave and have an opportunity to interact before the patient leaves. Hospitals generally refer to this as “leaving against medical advice.” The Office of the Inspector General and CMS refer to both of these scenarios as “voluntary withdrawal” of the patient’s request for evaluation or treatment.59,93

Leaving Without Being Seen

If a patient walks out before the MSE and later has an adverse medical result, the burden will be on the hospital to prove that the person left voluntarily and was not denied examination or treatment by the hospital.52,90

Hospitals need to have a policy and practice for LWBS patients that adequately document pertinent findings and protect the hospital from liability. In most hospitals, the staff calls the patient and checks the waiting area at least three times before declaring that the patient has left the department. These serial checks, with time of day performed, should be documented on the patient’s record, and once it is evident that the patient is no longer present, the record should be reviewed on a timely basis by the emergency clinician on duty. If the reviewing clinician discovers something of concern regarding the patient’s chief complaint or triage data, the person can be contacted and encouraged to return to the ED. The registration papers, triage records, nursing documentation at triage, and emergency clinician’s review and documentation of that review should be kept in the patient’s permanent record. These records should be retained for a minimum of 5 years to protect the institution should the interaction ever be the subject of a retrospective EMTALA investigation or litigation on behalf of the LWBS patient.49

Leaving Against Medical Advice

If hospital personnel are aware that a patient intends to leave before completion of the MSE or stabilizing treatment for whatever reason (eg, tired of waiting, changes mind, concerned about cost of care), the hospital should handle and document the interaction carefully to avoid EMTALA or medicolegal liability (Box e11.5). In each case, the following steps should be taken:

1. Inform the patient of the hospital’s obligation under the law. The ED staff should inform patients of their rights under the EMTALA to receive medical screening and any necessary stabilizing treatment from the hospital, regardless of their ability to pay for that service.

2. Determine the patient’s competence. Only legally competent persons can refuse necessary medical care. For example, alcohol-intoxicated patients who present to the hospital with medical complaints cannot be allowed to leave the hospital without examination and treatment until it is determined that they are legally competent to make such a decision.

3. Explain the risks and the benefits to the patient. For patients to make an informed consent to voluntarily withdraw their request for services, they need to understand the benefits and the risks of withdrawal before refusing examination and treatment. These risks and benefits should be specific to the patient’s chief complaint.

4. Secure the patient’s written informed consent to refuse care. The hospital should take all reasonable steps to secure the patient’s written and informed consent (ie, obtain a signature) to refuse medical care. A standard form should be used that contains space for documentation of the patient’s competence, the risks and benefits discussed, and whether the patient’s family was available to be involved in the discussions. If the patient refuses to sign the form and simply walks out after the interaction with the hospital, the person who discussed the issues with the patient and witnessed the patient’s refusal should sign the form and document the interaction.

5. Offer alternative care within the scope allowed by the patient. It is outside professional practice standards to respond angrily, to act vindictively, or to punish patients when they decide
**INFORMED CONSENT TO REFUSE EXAMINATION, TREATMENT, OR TRANSFER**

I understand that the hospital has offered: (Check all that apply).

A. To examine me (the patient) to determine whether I have an emergency medical condition, or

B. To provide medical treatment or to provide stabilizing treatment for my emergency condition, or

C. To provide a medically appropriate transfer to another medical facility.

The hospital and physician have informed me that the benefits that might reasonably be expected from the offered services are:

[Blank line]

and the risks of the offered services are:

**Fig. e11.2.** Leaving against medical advice form: Informed consent to refuse examination, treatment, or transfer.

to leave against advice by refusing to provide alternative treatments, medications, analgesics, or discharge instructions. Patients always get to define the scope of medical services that they are willing to accept. Accordingly, an appropriate strategy is to negotiate and cajole them into allowing the best possible care under the circumstances that they define. Negotiation aims for the best alternative that the patient is willing to accept, even if that means providing less than optimal treatment. Pain medications should never be withheld because the patient will not accept the recommended treatment plan. This “strategy” is cruel, further alienates the patient, and serves
BOX e11.5

Protocol for Management of Leaving Against Medical Advice Cases in the Emergency Department

- Always involve the emergency clinician.
- Involve the family or the patient’s personal physician whenever possible.
- Explain the risks and benefits specific to the patient’s condition; “You could die” alone is too generic.
- Explain any alternative treatment options to the patient.
- Ascertained the patient’s capacity to make informed medical decisions: “When in doubt, don’t let ‘em out!”
- Have the patient and at least one witness sign the leaving against medical advice form.
- If the patient refuses to sign the leaving against medical advice form, a member of the hospital staff should sign the form stating that the patient refused to sign the form.
- Always still provide the best possible treatment within the scope allowed by the patient, including antibiotics and analgesics when warranted.
- Provide appropriate discharge instructions and welcome the patient to return to the ED at any time if he or she reconsiders and decides to accept the recommended care.
- Document discussions with the patient, the risks explained, and the patient’s medical decision-making capacity and understanding of the ramifications of leaving against medical advice in the medical record (and in real time, not hours after the patient has left the ED).

ED, Emergency department.

no useful purpose. Moreover, patients should always be invited to return to the ED (or encouraged to see their private physician) if they change their mind and become willing to accept the recommended treatment. A patient’s refusal of the more appropriate treatments as well as communication of offers to provide treatment within the circumstances proscribed by the patient should be delineated.

6. Document the interaction in the patient’s hospital record. The medical record, preferably a dictated and transcribed medical record, should accurately relate the interaction between the hospital and the individual refusing ED care. The record reflects the hospital’s conformity to the law and the patient’s leaving of his or her own accord—specifically, the risks of refusing the examination and the reasons for the patient’s refusal. Documentation of the reasons for refusal provides evidence that the hospital did not economically coerce or in any way financially deter the patient from remaining for the MSE. The chart should clearly indicate that the patient did not leave the department on the basis of a “suggestion” by the hospital concerning any financial issues.

Parent or Guardian Who Refuses Care or Blood Transfusions for a Minor

In general, state laws support parental control of health issues affecting their children. However, the state will not allow parents to deny children needed emergency medical care under the doctrine of parens patriae, the state’s paternalistic interest in children. All states empower emergency clinicians to intercede under their child abuse and child neglect laws. When a child’s injuries are potentially life-threatening, the emergency clinician can take custody of the child under the child abuse laws and provide indicated treatment, including blood transfusions. In deciding whether to act, the when-in-doubt rule definitely applies, and all jurisdictions statutorily protect clinicians from criminal and civil liability for acting in good faith to protect children.

The courts have specifically addressed the issue of Jehovah’s Witness parents attempting to refuse emergency blood transfusions for their minor children. All jurisdictions hold that a parent’s right to freedom of religion does not include the right to deny life-sustaining medical intervention for that person’s children. Some states specifically address the issue of overriding parental refusal of indicated medical intervention by statute. In North Carolina, for example, if the parents refuse to consent to treatment and the delay to obtain a court order would seriously worsen the child’s physical condition or endanger the child’s life, and if a second clinician agrees that the procedure is necessary to prevent immediate harm, an emergency clinician can render treatment without parental consent. If a second clinician cannot be contacted before treatment is initiated, the emergency clinician may still perform the indicated therapeutic intervention without parental consent.

Conversely, courts refuse to rule against the parents’ wishes when the child’s medical condition is not serious or life-threatening. If there is no life threat or potential for serious impairment, the parents’ refusal should be respected. Parental refusal of indicated nonemergency medical treatment is usually statutorily defined as “child neglect,” which is not legally sufficient to take custody of the child. Child neglect should still be reported to the appropriate authorities; treatment for the child can then be obtained under a court order.

Jehovah’s Witnesses

Adult Blood Transfusions

Jehovah’s Witnesses and the issue of blood transfusion present difficult medicolegal issues in the ED. State courts may have widely divergent views on the issue, and no clear-cut answers exist. However, the current trend is granting patients greater autonomy to refuse blood, even when the state asserts compelling interests to override a person’s refusal.

General principles of consent and the when-in-doubt rule apply, but hospitals and medical staff also should develop policies and procedures in advance to resolve potential conflicts with the Jehovah’s Witness patients in the community; coordinate the management of each case with hospital legal counsel, in contact with a judge who can issue court orders when appropriate, if time allows; have other clinician consultants write notes of agreement regarding the need to give blood; and communicate effectively with patients and family, in advance when possible.

Competent Adult

The courts have found that “the competent adult has the right to refuse a transfusion regardless of whether his refusal to do so arises from fear of adverse reaction, religious belief, recalcitrance, or cost.” This applies “even though we may consider a patient’s beliefs unwise, foolish, or ridiculous.” However, even this right is not absolute. If the patient’s refusal conflicts with compelling state interests such as the preservation of life, the prevention of suicide, or the protection of innocent third parties, the courts may order transfusions despite the person’s objections. Previously, typical scenarios in which the courts overrode a competent person’s refusal included cases involving pregnant women to protect the life of the fetus, mothers of young children to promote the general welfare of the children, and a sole supporting father or mother to prevent offspring from becoming wards of the state. Some courts, however, have significantly restricted the hospital’s
or state’s ability to assert compelling interests challenging a competent person’s right of self-determination.102

**Unconscious or Medically Incompetent Adult**

In an emergency, if the Jehovah’s Witness’s beliefs are unknown, physicians may transfuse the patient because consent will be implied under the emergency doctrine. It is irrelevant if the spouse, mother, or other family members adamantly refuse to allow the transfusion for religious reasons. The state’s compelling interest in preserving life outweighs the family’s expression of the patient’s religious preferences.98,103

When a Jehovah’s Witness’s beliefs and transfusion preferences are known in advance but the patient is incompetent at the time of the emergency, the courts tend to accept objective evidence of the patient’s wishes. For example, a signed card carried by the patient that identifies him or her as a member of the Jehovah’s Witnesses and sets out the religious objection to blood transfusion may be accepted as adequate evidence of the patient’s intent. Like a form of advanced directive, it is binding on hospitals and emergency clinicians. In a number of states, if the card is dated and signed before two witnesses, it is statutorily valid.104 Even if the blood refusal card does not conform to a state’s advance directive statute, it should be considered strong evidence but not necessarily determinative of the Jehovah’s Witness’s wishes. Advance directives are merely a means to express an individual’s rights and are not the exclusive means to express those rights legally.98 Jehovah’s Witnesses increasingly use state statutorily defined advance directive methods to legally express their intentions.98,102 Emergency clinicians should, naturally, be certain the card or advance directive actually belongs to the patient.

**REPORTING REQUIREMENTS**

All states require hospital EDs to report certain events, such as deaths, violent acts, animal bites, or child abuse; or illnesses, particularly those of epidemiological concern, to local public health authorities. The state’s primary intent is to prevent the spread of communicable diseases, to protect its citizens from disease and violence, and to prosecute criminal acts. In each instance, the state statute overrides patients’ rights of confidentiality. The statutes typically also provide clinicians with immunity from civil liability or criminal prosecution if the reporting is done in good faith.

All EDs should maintain up-to-date lists of diseases and incidents that must be reported to the state. The process and responsibility for appropriate reporting should be clearly articulated in departmental policy.

**KEY CONCEPTS**

- Emergency Medical Treatment and Active Labor Act (EMTALA) governs virtually every aspect of hospital-based emergency services. Hospitals and emergency clinicians need to address the following issues to ensure compliance with the law:
  - Adopt (and enforce) a hospital-wide EMTALA policy, as well as emergency department (ED)—specific policies.
  - Educate all appropriate hospital staff and medical staff.
  - Define the hospital’s standard ED medical screening examination (MSE) process, including identifying “dedicated emergency departments” and designated “qualified medical personnel” to perform the MSE, as defined by the government.
  - Establish the hospital’s patient stabilization procedures and documentation.
  - Do not delay access to the MSE, stabilizing care, on-call physicians, or transfer on account of or to inquire about the patient’s insurance status (EMTALA’s “no-delay provision”).
  - Address the ED/outpatient registration procedures and payment collection systems.
  - Implement processes and procedures regarding patient refusal of the MSE, stabilizing treatment, or transfer.
  - Implement an effective ED physician on-call system, with written duties and responsibilities.
  - Create a uniform system and “transfer packet” for transferring patients out of the hospital.
  - Create a system for accepting or rejecting patient transfers from other facilities.
  - Institute appropriate documentation requirements for ED medical records, a “central log” for patients presenting to the hospital, transfers, and on-call lists.

- Post required “signs” in areas used for MSEs, including the ED, Labor and Delivery, and psychiatric intake centers.
- Monitor and quality assurance review the hospital’s EMTALA compliance.
- Draft a policy and procedure to report suspected EMTALA violations to Centers for Medicare and Medicaid Services (CMS).
- Review the potential application of EMTALA to the hospital’s outlying facilities, such as Urgent Care Centers, or Ambulance/Helicopter EMS Services.
- Review disasters plans and public health emergency responses for EMTALA issues.
- Draft and use legally-approved EMTALA forms to achieve/document compliance.
- Whenever emergency clinicians are in doubt about the legality of a situation, they should “do what you believe to be in the patient’s best interest and worry about the legal consequences later.”
- Consent for minors in the ED is a non-issue. Consent is a creature of state law; EMTALA pre-empts state law, and it requires the ED to provide a MSE and stabilizing treatment to all minors presenting to the ED.
- Emergency clinicians should be reticent to allow patients to leave the ED against medical advice. The capacity to make reasonable medical decisions can easily be affected by alcohol, drugs, pain, or any number of medical conditions. “When in doubt, don’t let ‘em out” should be the guiding principle. The courts (and public opinion) will bend over backward to protect clinicians who act in the best interests of the health and safety of their patients.

e11.1. Which of the following is a common source of liability for failure to comply with the Emergency Medical Treatment and Active Labor Act (EMTALA):
A. Failure to comply with written hospital policies and procedures.
B. Failure to diagnose an emergency medical condition (EMC).
C. Failure to properly treat an admitted patient who is boarded in the emergency department (ED) while waiting for an intensive care unit (ICU) bed to become available.
D. Failure to stabilize a patient after admission to an inpatient unit.
E. All of the above.

Answer: A. Hospital policies become the hospital’s standard under EMTALA. Thus, failure to comply with written policies, what Dr. Bitterman terms “failure to follow your own rules,” becomes an EMTALA violation when the policies are related to the medical screening and stabilization of patients in the ED.

e11.2. Which of the following violates the Emergency Medical Treatment and Active Labor Act (EMTALA):
A. A 7-hour wait after triage to be medically screened by the emergency clinician.
B. Boarding an admitted patient in the emergency department (ED) for 72 hours after the patient’s physician has accepted the patient for admission.
C. Delaying the patient’s access to an ED bed by declining to promptly accept the patient from an arriving emergency medical service (EMS) unit or by failing to immediately triage or evaluate the patient to determine if the patient can wait on a stretcher with the EMS folks until a bed becomes available.
D. Delaying the patient’s medical screening examination (MSE) in the ED to triage the patient, and then for the emergency clinician to see the patients in the order based on the triage nurse’s perception of the patients’ acuity.
E. All of the above.

Answer: C. Centers for Medicare and Medicaid Services (CMS) guidelines require the hospital to immediately triage ambulance patients arriving to the hospital’s ED.

e11.3. A 73-year-old woman is brought by private ambulance to the emergency department (ED) for shortness of breath. Due to ED overcrowding, there are several ambulance stretchers in line ahead of her at triage. At what point does the hospital “accept responsibility” for this patient?
A. When she was placed in the ambulance
B. When the ambulance arrived at her home
C. When the ambulance arrived on hospital property
D. When the patient is seen by the emergency clinician
E. When the patient is seen by triage personnel

Answer: C. The Emergency Medical Treatment and Active Labor Act (EMTALA) defines the time of acceptance of responsibility as when the patient “comes to the ED.” In its EMTALA regulations, the Centers for Medicare and Medicaid (CMS) defines the term “comes to the ED” to include anywhere on hospital property, so the hospital’s duty and responsibility for the patient is triggered when the ambulance arrives on hospital property.

e11.4. A physician on-call for the hospital’s emergency department (ED) has a duty under the Emergency Medical Treatment and Active Labor Act (EMTALA) to come to the ED under which of the following circumstances?
A. If asked to help stabilize a patient in the ED who has an emergency medical condition (EMC)
B. To help transfer a stable patient to another acute care hospital that has a specialist available that is not available at the transferring hospital
C. When asked to consult on a patient who has been stabilized in the ED and is being admitted by the patient’s primary care physician
D. Whenever requested to come to the ED by the emergency clinician on-duty
E. All of the above

Answer: A. Under the EMTALA, the on-call physician only has duty to come to the ED if needed to help determine whether the patient has an EMC or to stabilize an EMC. Any other requirements concerning when the on-call physician must come to the ED are governed by state law and/or by the hospital’s medical staff by-laws, not by EMTALA.

e11.5. According to the Centers for Medicare and Medicaid Services (CMS), which of the following patients may a hospital with specialized capabilities and available capacity refuse to accept in transfer solely because the patient is uninsured?
A. A patient with an unstable emergency condition admitted to observation at another hospital that is unable to stabilize the patient’s condition
B. Any patient the hospital chooses to reject
C. An emergency department (ED) patient with an unstable emergency condition who is at another hospital that is unable to stabilize the patient
D. An inpatient with an unstable emergency condition at another hospital that is unable to stabilize the patient

Answer: D. CMS guidelines state that hospitals do not have to accept an “inpatient,” as defined by CMS, in transfer from another hospital under any circumstances, even if its decision to decline to accept the patient in transfer will result in the patient’s death.

SUMMARY

KEY CONCEPTS

• Be cognizant that the work of health care occurs within a complex socio-technical system composed of five interrelated components: people, tasks, technology and tools, physical environment, and organizational conditions. A change in even one component has an impact on other parts of the work system and, ultimately, safety.
• Don’t count errors. Patient safety and mitigation of risk emerges from multifactorial interactions within the clinical work system. Incidents of patient or staff harm are most often the result of system failures, not individual human error.
• Process improvements to clinical care often have “unintended consequences” elsewhere within the work system. Partner with cognitive, behavioral, social scientists and engineers to reduce the likelihood of this and improve adoption by workers.
• Don’t set up reporting systems without the resources to fully analyze the reports.
• Safety is a complex dynamic “non-event” requiring minute-to-minute risk mitigation. Don’t look for technological “quick fixes” for creating safety within health care.

CHAPTER e12

Process Improvement and Patient Safety

Shawna J. Perry | Robert L. Wears

PRINCIPLES

Background

The overall process of an episode of patient care in the emergency department (ED) begins with the initial decision by the patient (or caregiver or family) to seek emergency assistance and ends with the patient’s disposition and follow-up. The care process is highly complex, with many separate components, people, and interfaces with other processes in the health care organization. This complexity provides many opportunities for process failures and adverse outcomes.

Although adverse events and failures in health care have been studied for decades, most health care professionals were largely unaware of it. This unawareness began to change in the early 1990s when the Harvard Medical Practice Study reported that almost 4% of hospitalized patients suffered significant adverse events during their care and attributed a large proportion of those to “human error.” Although that study noted that failures in ED care accounted for only approximately 3% of all adverse events in hospitals, the authors (who did not have ED experience) judged more than 90% of ED events to be preventable. This study and others ultimately led the Institute of Medicine (IOM) to issue a report in 2000 titled To Err Is Human: Building a Safer Health System. This report provoked the interest of the media and the general public, and it thrust the issue of safety in health care onto the national agenda. The major accomplishment of the IOM report was the introduction of some of the fundamental concepts regarding safety in complex systems for the first time into the world of health care. The most transforming concept was the idea that most failures in care are not the result of bad decisions or bad individuals but instead are intrinsic properties of the processes of care in the health care system. Thus efforts to reduce these failures should be focused on changing the processes of care rather than on identifying, retraining, or punishing the workers.

The response within health care was mixed. Most health care professionals focused on the projected number of deaths, arguing that they were either too high or too low; and a third, smaller group argued that the concept of error is essentially contestable and thus an approach aimed at counting errors is fundamentally flawed. The transforming concept of “system failure” rather than “human error” gradually gained acceptance, despite going against the natural human tendency to believe that individuals cause “human error,” resulting from the actions of a few aberrant practitioners who were not sufficiently accountable or attentive to safety. The prominence of educational efforts as responses to root cause analyses of adverse events testifies to the persistence of this “blame and train” mentality. Punitive measures, such as suspension, termination, or in extreme situations, criminal indictment of health professionals caught up in a medical mishap, are still all too common.

This chapter takes a different perspective. It views safety in health care as an emergent property of a complex, adaptive system, consisting of multiple interdependent components that are strongly interactive, such that a change in any one reverberates throughout the entire system at a speed and in ways that are difficult to predict in advance. Especially in the ED, safety is a dynamic activity; it ebbs and flows from minute to minute as it is being constantly created and destroyed by the dynamic nature of risk in emergency care and the performance adjustments and adaptations of staff.

Socio-Technical Work Systems

Health care today has evolved far away from its origins in independent practitioners acting as isolated agents. Today’s socio-technical work system requires the integration of humans, tools, technologies, and context to deliver a wide variety of clinical care in numerous settings from hospitals to free standing EDs. The interactions among workers, technologies and the organization determine the work outcome of the system, and in most cases the interactions among components are more important than the components themselves.

For example, unexpected downtime of two dialysis machines for several days in a dialysis unit markedly delays patients’ treatments, increasing the risk of cardiac and respiratory complications from hyperkalemia and fluid overload. This results in an increased number of blood draws to check potassium levels, with increasing risk of needle sticks for workers, as well as the risk of internal shortages of medications for managing hyperkalemia. There may also be organizational consequences, such as overtime pay for dialysis staff to accommodate patients whose treatments were delayed. Finally, there is also the potential for intensive care unit (ICU) admissions for patients who become unstable awaiting dialysis. Hence, any change in a work system, no matter how small, has implications for the system as a whole. This is encapsulated in the systems thinking adage that in a complex system, you cannot change only one thing.

Carayon and colleagues’ Systems Engineering Initiative for Patient Safety (SEIPS) model (Fig. e12.1) is a useful representation of health care as a socio-technical work system and its relationship to patient safety. This model views work systems as composed of five interrelated components: People who do the work (or who are being worked on); these people perform a range of tasks using...
technologies and tools. The performance of these tasks occurs in a physical environment under specific organizational conditions. The interaction of these five components produces the various outcomes that we desire.

The bi-directional arrows among the five components of the work system demonstrate their interdependence and reciprocal influences on each other. For instance, a failure of a blood analyzer (technologies and tools) in the laboratory results in a delay in reporting of laboratory results. This in turn causes a delay for clinical workers and patients (people) in need of final results for discharges. The delay in discharges results in further delays in moving admitted ED patients to the wards, resulting in boarding (people and physical environment). In turn, this increases the ED workload (tasks) and causes overcrowding that requires ED workers to deal with an overcrowded workspace (physical environment). The problem then requires action by the organization to forestall dissatisfaction, loss of reputation, and staff turnover (see Fig. e12.1).

The SEIPS model represents the hydraulic nature of interactions among components in a work system, in that changes in any component have varying degrees of impact on the others. This systems-based view of clinical work has several implications. First, safety and performance are ultimately functions of how well the work system as a whole is able to adapt and compensate for perturbations arising from numerous internal and external sources. Second, because the components are coupled, there are no isolated, “silver bullet” fixes; every change will have both direct and indirect effects on other components, which can be difficult to predict. Third, because of this coupling, such systems cannot be directly controlled. However, all is not lost, because even though they cannot be controlled in a mechanical, linear sense, they can be influenced; actions taken by managers and workers in the system can set the stage for desirable or undesirable outcomes to emerge, even though they do not directly cause them to occur.

### Safety and Risk in Dynamic Work Systems

Safety is commonly thought of in terms of a lack of danger and risk or the absence of something going wrong. This is predicated on the hidden assumption that safety is somehow the natural and normal state of the system and that adverse events are aberrancies that must have some special cause. This assumption is common in health care and has led to an emphasis on reporting systems and incident counting efforts to measure safety.

This perspective as been widely embraced, because it fits well with rationalized, linear notions about how clinical work is (or should be) done (ie, patient flow is registration → triage → waiting room → treatment room → nurse assessment, and so on). This view of work-as-imagined (WAI) assumes that clinical tasks can be standardized and managed by sets of rules, policies, and procedures. It also assumes that unsafe situations are the result of failure or deviation from policy, procedures, and protocols, and so reducing these deviations is the key to safety: If workers just follow the rules, then patients will be safe.
Resilience

WAD often involves resilient behaviors that respond to current or potential problems that increase risk or delay completing the clinical work. For example, on a busy day a clinician asks for an intravenous (IV) line on a patient she has just seen before she goes to a resuscitation. The ED technician, seeing no lab has been ordered “draws a rainbow,” where he obtains blood from the patient and places a sample in every color of laboratory blood tube available. Organizational policy, however, requires blood not to be drawn until an order has been placed and a lab sticker generated to label each tube. The technician draws a rainbow without orders because he: (1) knows that the patient is a difficult stick and does not want to have her suffer through another painful blood draw; (2) anticipates that he may not be able to get back and perform another draw once orders are in because he might be pulled to another area; and (3) believes the patient looks ill, so the physician is likely order a number of tests when she returns.

This fairly simple workaround is an example of resilient behavior. The ED technician’s decision to draw the blood despite the organizational policy requiring orders for drawing blood addresses a number of existing and potential obstacles for the patient’s care. The technician’s modification of work processes contributes to the patient’s care and the ED’s overall effectiveness. The majority of resilient performances in the ED are hidden (in part because they involve bending the rules) and are done without any special thinking that “it’s time to be resilient.” Interestingly, seasoned nurses, technicians, and physicians can frequently be overheard orienting new staff to similar workarounds, because they have proven to help with workflow management and to benefit patient care.

Resilient performances can also occur across microsystems and specialties as illustrated in the following case:

A 24-year-old non–English-speaking sailor presents to the ED with 3 days of intermittent pain and numbness in his left leg with recurrent short episodes of dizziness and low blood pressure. Upon physical examination, the emergency clinician notes a pectus excavatum deformity; a dramatically abnormal chest radiograph and intermittent hypotension made the diagnosis of aortic dissection almost a certainty. A page to cardiovascular surgery goes unanswered, an atypical occurrence in this ED. Based on a hunch that perhaps the cardiovascular team was in the operating room, she turns to the unorthodox solution of calling the operating room and asks the nurse to pull up the patient’s chest x-ray on the computer in the operating room, thinking this will most easily and effectively alert the surgeon to the need. This novel method for escalating an urgent case gets the patient into the operating room shortly after his arrival in the ED.

This case demonstrates resilient behavior not only by the emergency clinician but also by the surgical team in the operating room. Members of the team, including the surgeon, were open to participating in an unorthodox method of consultation, a workaround that deviated markedly from prescribed protocols for consultation and escalation. This is an important example of a “workaround” strategy and how “extra steps” contribute to resilience.

### SOURCES OF FAILURE IN EMERGENCY CARE

Many characteristics of emergency medical practice make it vulnerable to failures (Table e12.1). Safety research in emergency care demonstrates a wide range of known and unknown contributors to patient safety and highlights the importance of the work processes that overlay this complex work environment. For instance, Morey reported that specific training of emergency clinicians and nurses to work together in teams led to reductions in failures and improved performance. Perry and Fairbanks identified a number of unexpected yet highly consequential failures of information technology (IT) that were difficult to detect, some occurring during emergency resuscitations. Wears and Perry noted ergonomic shortcomings in the workplace and pointed out their potential to contribute to failures in care. Hall identified significant delays related to ED layout, with time to assessment of chest pain patients being longer for patients placed behind a door or who were 25 feet or farther away from the physicians assigned to

*Intrinsic factors are intimately part of the nature of emergency care and as such are not amenable to change but instead must be compensated for.

*Extrinsic factors are in principle manageable and typically relate to resource constraints.

*Low signal-to-noise ratio refers to the low likelihood of a critical diagnosis compared with a benign diagnosis for similarly presenting symptoms and findings (eg, subarachnoid hemorrhage vs. tension headache).

*Surge phenomena are the rapid changes in volume and acuity routinely experienced in many EDs.

ED, Emergency department.
care. This section focuses on some of the principal factors that contribute to adverse outcomes and how they might be better managed to improve safety.

### Communication and Interruptions

Chisholm reported that emergency clinicians are interrupted, on average, approximately once every 6 minutes and that two-thirds of those interruptions cause a change in task; this is important because both interruptions and task switching frequently lead to process failures. Fordyce reported that self-detected errors occurred in almost 20% of all ED cases but that only 2% were associated with adverse events. Fordyce's work emphasizes that errors are ubiquitous but only rarely combined with other factors to produce adverse events, and it supports the notion that focusing on eliminating errors is not likely to be a productive strategy for improvement.

### Workspace Design

Two frequently overlooked contributors to lowered safety in any work environment are (1) the design of the workspace and (2) the engineering of the tools, technology, and procedures used to perform the work. This is especially true for EDs, because the majority were not designed for the work currently being done in them. ED caregivers are required to adapt to the space by creating “workarounds” to cope with the limitations and impediments of the workspace.

Consistency is rarely found in equipment across or between areas. For instance, the monitors in the ED are often not the same as those used in the radiology department or ICU. In addition, tools and technology are seldom developed or assessed for their “user-centered design” or ability to be integrated into existing workspace and the associated hazards for doing so. This is most apparent with regard to health IT, which is often introduced for improvement of safety and quality; however, embedded latent features that can produce clinical failures that are “hard to see” have been demonstrated.

A study of computerized physician order entry by Koppel showed that the software facilitated 22 types of medication error risks, such as displays that prevented a coherent view of the patients' medications or inflexible ordering formats that led to wrong orders. Other contributors to IT failure within health care are the lack of usability testing and failure to address the impact of the new technology and changes in clinical work after implementation.

The contribution of poor design to the difficulty in maintaining safety in a health care environment is generally overlooked by staff members who cope with these difficulties as “part of the job.” Vigilance is the common solution, but despite caregivers’ best efforts it cannot be sustained, given competing demands for their attention. This increases the risk that a failure not being recognized will be linked to the workplace, the procedures, or the equipment, despite being “tightly coupled” to any or all of these.

### Crowding

ED crowding has long been recognized as a major source of time-delay failures and a threat to patient safety. Such delays are not simply an inconvenience to the patient but may give rise to significant adverse events. For example, patients with atypical presentations of severe illness who have been mis-triaged to low levels of acuity may experience inordinate and, occasionally, fatal delays. In other cases, such as community-acquired pneumonia, cellulitis, and lacerations, more expedient care may significantly improve the outcome of the illness. A significant proportion of patients who leave the ED without being seen may have serious illness and incur delays in diagnosis and treatment. At the other end of the process, when the patient is ready for admission to the hospital from the ED, further time-delay errors may occur. Not only do such delays create throughput problems and contribute to crowding, but they also create discontinuities in care and may lead to adverse events that are difficult to identify, because they manifest after the patient has left the ED. The need to adapt to the cognitive overload posed by crowding contributes to greater use of mental shortcuts and less accurate decisions in an efficiency/thoroughness trade-off (see later).

### Information Gaps

Missing information is common in emergency care and can significantly affect quality of care. Hospital records, especially discharge summaries, details of past medical history, and other important information are often difficult to access in an expedient manner; and even with electronic medical records, pertinent information may be difficult to locate. Referral notes sent by family physicians with the patient may not reach the emergency clinician or may not contain relevant or significant details. In these situations, clinicians make decisions and take action on the basis of incomplete, limited, or erroneous information. Emergency clinicians often end up not seeking additional or clarifying information because of time pressures, patient volume, or limited methods to obtain more information (eg, the referring physician’s office is closed), essentially accommodating to this “gap” in continuity of care and the associated increase in patient risk.

### Performance-Shaping Factors

A wide variety of ambient, systemic conditions contribute to the majority of adverse events and near misses that occur in the ED (see Table e12.1). Some performance-shaping factors are an “intrinsic,” part of the milieu of emergency medicine and thus not amenable to direct control (eg, cognitive workload, multiple distractions and interruptions, and high acuity). These factors must be managed by strategies to buffer or to mitigate their effects. In contrast, other “extrinsic” performance-shaping factors typically reflect limitations of resources (eg, staffing ratios, production pressure, and ED layout).

### Violation-Producing Factors

Although at first one might think that violations of organizational policies, rules, and procedures would always be causes of failures and adverse events, the modern approach to safety has pointed out that some violations are actually necessary for the safe functioning of the system, and others fall somewhere in between. Aside from recklessness, drug use on the job, moral failings, and other egregious acts, research in other domains has identified other factors that are associated with the occurrence of rule and safety violations (Box e12.1). The “normalization of deviance” is an accumulated acceptance of small variances from safe operating conditions that develops over time, ultimately compromising safety. This is evidenced in overtaxed EDs coping with crowding of patients (eg, examining and managing of patients in hallways). Violations can also occur in response to perceptions of authority. They may occur through a directive supporting violation from an authority figure (eg, nursing supervisors order admitted patients moved to inpatient beds without calling to report if there are delays in reaching inpatient nurses), the absence of a disapproving authority (eg, physicians leaving shifts early but the medical director does not address the behavior), or an individual’s self-perception that he or she is authorized to disregard or to deviate from prescribed procedures (eg, ED electrocardiograms done on patients in chairs because there are no available stretchers). It is important to note that violations differ from workarounds in that...
Violation-Producing Factors

violations tend to undermine safety and increase risk, whereas workarounds and extra steps are resilient actions in support of safety and mitigation of risk.

Fluctuations in mood can also contribute to violations for a variety of reasons and will result in inconsistent clinical performance; for instance, men are more likely to break safety rules and to engage in more risk-taking behavior than women. Risk-seeking and risk-averse attitudes are associated aspects of decision-making in the ED.

Teamwork

Good teamwork is essential to the safe practice of emergency medicine, but emergency caregivers are not trained or evaluated as teams. Teamwork training in other fields, such as aviation, has been successful in reducing failures related to poor communication, cross-monitoring (observing others’ behaviors to reduce risk of failure and share workload), and authority gradients (both within and between professions). Work on transferring teamwork training principles to emergency medicine suggested that teamwork failures are involved in approximately 40% of malpractice cases. The lack of cross-monitoring across team members and the failure of advocacy or assertion on behalf of the patient by caregivers to avoid patient harm were two of the factors most frequently identified. A multidisciplinary teamwork training course implemented in eight EDs showed a significant improvement in quality of team behaviors and a sixfold decrease in observed clinical errors. Teamwork is not a specific fix for any one type of error, but it should be viewed as one type of adaptable human factor intervention; a set of teachable skills and behaviors capable of increasing system resilience and safety, which are hallmarks of high-reliability organizations.

Teamwork training requires institutional and ED leadership to be fully committed to the process embarking on a training program. Resistance to behavioral change is common, and it will be necessary to demonstrate the clinical relevance of this training. High-fidelity medical simulation supported by audiovisual feedback offers an educational methodology to help clinicians and staff understand the necessity of behavioral change. A major unanswered question is how to embed teamwork behaviors into medical training and how to sustain the behaviors over time.

Efficiency/Thoroughness Trade-Off

EDs are under constant pressure to reduce waiting time and speed the throughput of patients. This risk forces a trade-off between improving efficiency and thoroughness referred to as the efficiency/thoroughness trade-off principle. This tradeoff is seldom directly acknowledged in official policies, but it can invariably be observed in the ED, especially when the volume is high. For example, the question “What is the one thing you are most worried about?” posed by a caregiver to a patient may indicate that efficiency is the priority and send a message that there will not be an opportunity to address all of the patient’s concerns or medical complaints. Although efficiency/thoroughness trade-off decisions are often not articulated explicitly, organizations and regulators implicitly and explicitly demonstrate the importance of efficiency in their monitoring of throughput goals, length of stay, patients leaving prematurely, and staffing and supply levels. Thoroughness in most settings often only arises from the hindsight bias that follows an adverse event. Although simultaneous improvements in efficiency and thoroughness are sometimes possible, eventually every work system hits a hard limit where improving one dimension degrades the other.

Authority Gradients

Humans in groups invariably sort themselves by degrees of authority. This hierarchy can be based on profession (physicians have greater authority than nurses) or organizational rank (attending physicians have greater authority than residents). These authority gradients can impede the free flow of information among team members if low-authority members are inhibited by differences in seniority, stature, expertise, profession, or social status. There are clear examples of cases in which authority gradients have been responsible for adverse events. A work environment in which all team members feel comfortable expressing their viewpoint, especially if it is a dissenting one, requires a cultural change that can begin with the physicians who occupy the highest authority position in the clinical setting. Authority figures can support a flattened hierarchy by openly recognizing the value of perspectives other than their own and eliciting them from other clinicians and staff (eg, asking a nurse what he thinks might be going on with a patient). Senior clinicians are in a powerful position to bridge gradients by fostering open communication through multidisciplinary rounds, demonstrating that they are approachable (eg, acknowledging staff by name), and using clinical narratives from their own experience that illustrate near misses and judgment failures.

Cognitive Processes

Patient care in the ED is a process of making clinical sense out of multiple sets of unfolding, fragmented, tangential, ambiguous, and interrupted stimuli. The goal of this process is an accurate diagnosis if possible or, much more commonly, a characterization of the problem, which can usefully guide actions, management, and disposition. Although many diagnoses, such as lacerations, dislocations, fractures, and foreign bodies, are self-evident, others (eg, chest pain, fever, headache, abdominal pain, and syncope) are often associated with high levels of ambiguity and uncertainty and are more likely to lead to problems. Cognitive biases can frequently be identified in retrospect after diagnostic failures, but the problem of hindsight bias makes this identification problematic.

Fatigue and Shift Work

Both fatigue and shift work contribute to performance failures, but relatively little research has been directed to their respective
Effects of Sleep Deprivation

Longer reaction time
Lapses in attention or concentration
Lost information
Errors of omission
Poor short-term memory
Poor mood (increased confusion, stress, and irritability)
Reduced motivation
Distractibility
Sleepiness
Poor psychomotor performance
At circadian low points
When sedentary
On long, difficult, or externally paced tasks with no feedback
In unchanging surroundings, particularly with reduced light or sound, or with low motivation, interest, or novelty

Rational Approaches to Shift Work

Optimize circadian-friendly schedules
Forward rotating (clockwise with circadian rhythms)
Rapid changes
Minimize consecutive nights (1 or 2)
24 to 48 hours off after nights
Allow social time, including some weekends
8-hour shifts (absolute maximum 12 hours)
Institute regular, predictable template
Practice proper sleep hygiene
Use a sleep-friendly room: Room-darkening blinds, "white noise" (eg, electric fan) or earplugs, no phones, family aware
Maintain a regular sleep routine
Try anchor sleep
Avoid caffeine, alcohol, and drugs
Prophylactic naps
Modulate circadian rhythms
Exercise
Consider bright light
Eat healthy
Eat a balanced diet
Avoid junk food
Keep regular mealtimes
Promote a healthy lifestyle and work style
Promote a personal healthy lifestyle
Educate friends and family about shift work issues
Educate colleagues about shift work issues
Advocate for department improvements in working conditions
Advocate for shift worker–friendly community services
Avoid pharmaceuticals
Use caffeine in moderation, prn
Do not use sedatives or stimulants
Avoid alcohol before sleep

The appropriate management of shift work and fatigue to improve patient safety is not well understood, and further research is needed in this area. In most high-hazard industries, the assumption is that fatigue and long, aberrant work hours lead to poor performance; however, in the health care industry, issues about discontinuity of care and difficulties in changing medical culture have obscured these concerns. Given that medical personnel, like all human beings, function suboptimally when they are fatigued, efforts to reduce fatigue and sleepiness should be undertaken, and the burden of proof should be in the hands of the advocates of the current system to demonstrate that it is safe. In the meantime, shift scheduling should be optimized to reduce the impact of circadian disruption, and ED personnel should practice good sleep hygiene. Some basic approaches are listed in Box e12.3.
Triage

Triage, or sorting by acuity, is by definition an abbreviated decision-making process that can never be completely safe because of the limited information available, the lack of time invested, and the variety of presentations of illness and injury. Also, there is a low “signal-to-noise” ratio for a number of serious conditions (ie, when the incidence of a serious condition is far exceeded by that for a benign condition, but the clinical presentations are similar). Inevitably, the triage process involves tradeoffs between sensitivity and specificity. Under-triage for a particular patient would have a greater potential for an adverse event than over-triage, whereas over-triage affects resource utilization and may have an impact on the care of other patients.

Triage assessments are important contributors to process failures and adverse events. Beyond treatment delays, which can occur with under-triage or be produced by over-triage, an incorrect assessment may be the triggering event that initiates a chain of failures. Geography can become destiny, and an inappropriate triage to a specific treatment area may create a bias in the minds of the treating clinicians and staff. The use of five-level triage systems for adults and children, with excellent inter-rater reliability, offers an opportunity to reduce the risk associated with under-triage.

Technical Procedures

The practice of emergency medicine requires proficiency in a wide range of procedures with varying degrees of difficulty. Patients who require procedures are at greater risk for adverse events. Contributors to this higher risk include problems with proficiency and a low frequency for use of higher risk procedures. Critical procedures, such as cricothyrotomy, pericardiocentesis, and endotracheal intubation, are rarely or less commonly performed; when they are needed, they are highly consequential events involving significant time pressure. An important challenge in emergency medicine is the acquisition and especially the maintenance of a requisite level of skill. Simulation techniques have considerable potential to ameliorate skill degradation, but require both capital and human investment to be effective.

Laboratory Tests

The interface between the ED and its ancillary services is critically important. Failures can occur at three phases of laboratory processes. Pre-analytic errors mostly occur through inappropriate collection of specimens because of lapses in technique, timing, and identification of both patient and specimen. Analytic errors refer to those that arise directly from the testing process. Post-analytic errors occur after the test result has been obtained and can take many forms (eg, keyboard entry errors, overlooked or lost data, and failure of results to reach the physician). Studies of a blood bank and a STAT laboratory found that the majority of failures occurred in the pre-analytic and post-analytic stages, with less than 5% in the analytic stage. Overall, the laboratory defect rate is less than 1%, but the number of exposures is large. Of the failures that do occur, up to 50% may have a moderate impact and up to 8% a severe impact on patient care.

Radiology Studies

Radiographic imaging is a critical aspect of diagnosis and management in the ED. Although patient identification and wrong-side problems are important sources of failure, the majority lie in interpretation. Assuming the radiologist’s interpretation to be the criterion standard, the rate of errors in interpretation by emergency clinicians may be as high as 16% for plain radiographs and more than double that rate for computed tomography scans. Clearly, not all misinterpretations are consequential, and emergency clinicians typically seek the advice of the radiologist when they recognize difficult interpretations. The introduction of digital imaging and picture archiving communications systems has resulted in new patient safety issues related to usability, the effect of monitor resolution on interpretation, and reconciliation of ED clinician and radiology readings. Significant interpretation errors can be detected with prompt review of all films by the emergency clinician and radiologist, but effective procedures are required to ensure that timely and appropriate feedback and review occur. This approach has been demonstrated to substantially reduce the rate of clinically important misinterpretations.

Transitions in Patient Care

The need for 24-hour access to care and the fragmented nature of health care delivery require the occurrence of transitions of care between providers, either within the ED (at shift changes) or between the ED and other care areas (when patients are admitted, transferred, or discharged). The shift “sign-over,” “sign-out,” or “handoff” is generally thought of as a communication activity performed for the transfer of clinical information, but it also embodies the transfer of responsibility and authority from one provider to another. The sign-over also conveys general situational awareness (eg, the state of the department, hospital, and city) and provides a forum for review of decision-making and treatment plans.

Although transitions of care have been studied in recent years, few of these efforts have engaged with the cognitive, behavioral, and social sciences essential to a deep and systematic understanding of the problem. When viewed superficially, sign-overs seem highly variable in their content, the number of individuals involved, the physical configuration (eg, walking, stationary, and at bedside), the tools used to facilitate the transition (eg, white boards, medical records, and written notes), and the length of the transition process; however, they have a fundamentally similar deep structure. Although widely regarded as providing a major contribution to adverse events, sign-overs also provide an opportunity for review of decision-making by clinicians and may provide opportunities for rescue and recovery by bringing “fresh eyes” to a patient’s case. Potential threats to effective transitions include:

• Interruptions during the turnover (eg, phone calls and sidebar conversations) can cause a loss of focus and lead to the omission of important information.

• Lack of consistent structure to the turnover: Although the traditional case presentation narrative is often followed (chief complaint, history, physical examination, initial laboratory results, impression, and plan), the case presentation format may not provide opportunities for noting pending or as yet uncompleted tasks.

• Patients are commonly “marked” in ways that can sometimes be helpful but sometimes harmful, especially for at-risk groups, such as the homeless, psychiatric patients, alcoholics, and drug abusers.

Common sense and well-meaning approaches, such as standardizing verbal content and compulsory use of sign-over checklists, risks extinguishing inherent latent safety features when implemented without deeper research of this complex and vital work tool for emergency medicine and health care overall.

Orphaned Patients

Orphaned patients are those who have suffered temporary loss or diminished supervision or accountability for their ED care. This may occur at several stages in the process. Patients who are seen
and assessed at triage and then wait in the waiting area are temporarily orphaned. Those who are brought in by paramedics sometimes remain on stretchers for hours before being admitted to the ED. Patients who leave without being seen or before treatment is completed have “orphaned” themselves. Patients can also be temporarily orphaned out of the ED for radiographic studies or other special tests. On occasion, patients get “lost in the shuffle” and are overlooked at shift change, or they may get “lost” after one or more consultations with other services. With prolonged wait times, occult conditions can progress to serious and potentially catastrophic levels. A significant cause of orphaning in some EDs is the “boarding” of admitted patients because no inpatient beds are available. In such cases, patients may be put in holding areas in or adjacent to the ED and receive sporadic care from a succession of caregivers who know increasingly less about their conditions. The risk of harm to patients caught in this “gap” within the ED is not well studied.

Medication errors constitute the largest proportion of failures in most studies, with failures occurring in all six steps of the process (prescription, transcription, dispensing, administration, monitoring, and discharge). Some EDs take on the dispensing role, obviating input from the pharmacy, where many errors are corrected. In addition, team communication errors can contribute to many failures—missed medications, wrong medications, and duplicate dosing. Pediatric patients are at higher risk; drug errors are no failures—missed medications, wrong medications, and duplicate addition, team communication errors can contribute to many.

Medications

The presence of a pharmacist on the clinical team has been shown to reduce medication errors in several settings. There is great interest in the potential for computer technologies, such as bar coding and computerized physician order entry, to enhance medication safety. However, despite this potential, there is evidence that such systems introduce new problems to replace old ones. The Institute for Safe Medication Practices has recommended that certain problem practices be avoided in writing orders or prescriptions. Success in this area will require more than just individual attentiveness; nurses, unit secretaries, and pharmacists will have to feel comfortable challenging improper use by physicians.

SUMMARY

The safe management of patients in the ED depends on a multiplicity of processes. All appear vulnerable to failure, yet all have the potential for improvement through judicious process management. Efforts by frontline workers will not be sufficient; considerable effort will be required at the administrative or “blunt end” of the system.

Safety in complex dynamic environments is itself dynamic. Safety is a “non-event,” because it is evidenced by the absence of things that should not or do not occur, such as administration of a medication to the correct rather than wrong patient. It cannot be banked for future use but is created by workers in a well-designed and supportive organizational environment. Achieving safe performance in settings such as the ED is analogous to fighting a guerilla war: There are no dramatic victories, but there are occasional horrific defeats, with no end in sight. Sources of risk are ubiquitous with the human factor critical to its mitigation on a minute-to-minute basis.

The establishment and maintenance of successful safety cultures within health care requires constancy of purpose by health care organizations, willingness to adopt new ideas and tools from outside of health care, and commitment to continued effort and investment.

CHAPTER e12: QUESTIONS & ANSWERS

e12.1. Teamwork failures in emergency medicine are involved in approximately what percentage of malpractice cases?
A. 10%
B. 20%
C. 30%
D. 40%
E. 50%

**Answer:** D. The lack of cross-monitoring by team members and the failure to demonstrate advocacy or assertion on behalf of the patient by caregivers in avoidance of harm are two of the most frequent factors cited.

e12.2. A 27-year-old woman presents with complaints of back pain. She has been to the emergency department (ED) a number of times for this same complaint. On the way to the medical screening examination, the emergency clinician is heard to mutter, “She's a drug seeker.” This is an example of which potentially negative process?
A. Authority gradient
B. Cognitive framing
C. Countertransference
D. Fatigue and shift work
E. Visceral bias

**Answer:** E. In addition to cognitive mental properties and the effects of fatigue/shift work, the emotional state of the physician can affect his or her decision making. This has been referred to as visceral bias. Health care workers are often less aware of the presence/function of factors such as economy of perception that may lead to stereotyping and adversely affect clinical interactions.

e12.3. Rational approaches to shift work include all of the following except:
A. Exercise
B. Forward rotating schedules
C. Sedatives
D. Use of sleep-friendly rooms (eg, dark cloth or blinds, white noise, ear plugs, family awareness of need to sleep)

**Answer:** C. Sedatives. The use of sedatives and/or alcohol should be avoided because each affects the effectiveness of sleep between shifts and therein the overall risk of medical errors and patient harm while working shift hours due to fatigue.

e12.4. Factors that affect emergency department (ED) performance and increase vulnerability to failure include:
A. Low-density decision-making, poor teamwork, low workload, hunger
B. Overcrowding, high levels of uncertainty, fatigue, ED layout
C. Overstaffing, low cognitive load, production pressure, low numbers of transitions in care
D. Physician salaries, consultation rates, multiple interruptions, medication shortages

**Answer:** B. Many intrinsic and extrinsic factors affect an ED's performance, undermining its functioning and making it more at risk for a medical mishap or patient harm (see Table e12.1). Although each choice contains at least one of these performance-affecting factors, only choice B contains four of the factors.

PRINCIPLES

The National Wellness Institute defines wellness as an active process through which people become aware of, and make choices toward, a more successful existence.1 Wellness is complex and multifaceted and includes a person’s physical, mental, and emotional health and wellbeing.2 Multiple recent studies suggest that physicians as a group, and emergency clinicians in particular, are unwell.3,5 In fact, emergency clinicians have the highest rate of burnout when compared to other specialties.2 Burnout can have a serious impact on a physician’s personal life and lead to chemical dependence, broken relationships, depression, and suicidal ideation.4,5,6 Of concern to the health care system as a whole, there is a serious impact on a physician’s personal life and lead to chemical dependence, broken relationships, depression, and suicidal ideation. Furthermore, physicians who experience burnout are more likely to change careers or retire early, amplifying the physician workforce shortage.3 This chapter outlines concepts related to wellness, discusses consequences of the lack of wellness and the impaired physician, and explores strategies for promoting wellness at the institutional, professional, and personal level.

SPECIFIC ISSUES RELATED TO EMERGENCY CLINICIAN WELLNESS

Stress

Stress is a nonspecific response of the body to any demand, and it can have both positive and negative effects. Without any demand, performance suffers. With too much stress, anxiety and exhaustion lead to poor performance (Fig. e13.1). Although all human beings experience stress, emergency clinicians face unique stressors, due to the nature of their work. The emergency department (ED) is a diverse and frequently chaotic environment. Patients arrive at any time of the day or night in an unscheduled manner, and the numbers, types, and acuities are unpredictable and can change at any moment. Patients are frequently in distress when they present to the ED, and many are dealing with life-threatening illness or injury. Patients do not come to the ED with their joy; rather, they arrive with their pain and anxiety, often severe. Some have language barriers, mental health issues, or alterations in their mentation that make them difficult to evaluate and present challenges for communication.

Emergency clinicians deal with death and dying on a daily basis and generally do not have time to process their feelings regarding these losses due to patient load and the need “to move on” to the next patient. Personal safety is also a major issue while working in the ED environment where exposure to acts of violence, verbal abuse, and risk of exposure to potentially life-threatening diseases are higher than in other practice settings. Add to all of the aforementioned stresses, the pressure for perfection, with the ever-present possibility of a missed diagnosis, with the attendant risk of a medical negligence lawsuit, and the continued focus on patient satisfaction, with the threat of a patient complaint and punitive action related to this, it is not difficult to understand how physicians feel burdened and constantly under pressure.

The 24/7 nature of emergency medicine also creates unique physiologic stress on the emergency clinician due to changing shifts and its impact on circadian rhythms. Shift work has been shown to lead to poor quality of sleep, fatigue, and mood disturbance; challenges to maintaining relationships; and difficulty coping with the demands of daily life.2,3,4

Faced with decreased hospital and community resources and growing public demand for emergency services, EDs frequently are stretched beyond capacity by sheer patient load and the boarding of admitted patients.4 This is further complicated by commonplace workforce shortages, nursing understaffing, and the lack of availability of on-call specialists. These issues have been shown to correlate with poorer patient outcomes and have led to a new culture where efficiency is often viewed as more important than providing safe, compassionate care.5

The introduction of electronic medical records (EMRs) has added a new stressor to emergency clinicians. Recent studies suggest that EMRs lead to increased administrative burden (more time charting, order entry, and so on) and less face-time with patients, resulting in decreased job satisfaction.6-8 The EMR also interferes with physician/nurse collaboration and the fulfilling sense of being part of a team and working together, as communication moves from face-to-face personal interaction to an electronic interface.

Burnout

The term burnout was first used by Herbert Freudenberger in 1974. It is defined as a prolonged response to chronic stressors, on the job, defined by three dimensions: emotional exhaustion, depersonalization, and a sense of reduced personal accomplishment.9-11 Eric Gentry and Anna Baranowsky described burnout as “the chronic condition of perceived demands outweighing perceived resources.” Although not all emergency clinicians will develop burnout during the course of their careers, the particular aforementioned stresses place them at increased risk.

Compassion Fatigue

Compassion fatigue has been described as burnout plus secondary traumatization. Secondary traumatic stress, which some describe as synonymous with compassion fatigue, is defined as the emotional and physical burden created by the additive trauma of helping others in distress that results in a reduced capacity and interest in being empathetic toward future suffering (Fig. e13.2).9,12 Risk factors for emergency clinicians developing compassion fatigue include being in situations where they are a “first responder” or when they share some identity with the people that they are providing care for.12 Along with leading to decreased empathy, compassion fatigue can also lead to sadness, grief, somatic complaints, detachment, anger, and changes in belief...
The Practice of Emergency Medicine

Lack of wellness is a major problem for emergency clinicians and one that can have a huge impact on their personal lives, their families, the profession, and the health care system. Although there is a growing body of literature on the problem of burnout and compassion fatigue, the research surrounding how to address these problems is still in its infancy. What little literature does exist supports a multifaceted approach to the problem at the institutional, professional, and personal levels. The focus should be on preventing burnout and impairment, not just on identifying the impaired clinician and providing treatment.

Incorporation of mindfulness and teamwork training for physicians has also been recommended by some research. A study by West and colleagues found that a 9-month bi-weekly 1-hour facilitated discussion group incorporating elements of mindfulness, reflection, and shared experiences improved work meaning and engagement and reduced depersonalization even 12 months after the intervention. The physical health of physicians has also been the focus of some institutions. A study out of the Mayo Institute demonstrated that an incentivized exercise program increased physical activity and quality of life for residents and fellows who participated in the program versus those who did not. When more than 2000 physicians were asked how their institution could help with stress and burnout, the top requests included the following: more ancillary support to help with charting (eg, scribes); onsite exercise facilities or classes; wellness initiatives; and education on managing stress and burnout.

Institutions can also provide monitoring programs for at-risk physicians and should have resources to help impaired physicians. Physicians themselves are not especially good at detecting their own burnout or impairment. Employee assistance programs or wellness committees can serve this role. Referral to state

**CONSEQUENCES OF LACK OF WELLNESS AND THE IMPAIRED PHYSICIAN**

Lack of wellness and resilience of emergency clinicians can have a significant impact on the care that they provide and the health care system as a whole. Stress, job dissatisfaction, and burnout have been shown to negatively impact quality of care and patient safety. Firth-Cozens and Greenhalgh examined physicians’ perceptions of the connection between work-related stress and patient care. Physicians perceived that work-related stress led to reduced standards of patient care (eg, taking shortcuts and not following procedures), increased irritability and anger at work, and increased errors related to patient care. Burnout is also associated with reduced workplace productivity due to increased absenteeism, job turnover and early retirement, probability of ordering unnecessary tests, and decreased time with patients.

At the far end of the spectrum of physician lack of wellness is physician impairment. The Federation of State Medical Boards defines an impaired physician as one who is unable to practice medicine with reasonable skill and safety due to mental or physical illness; due to a condition that adversely affects cognitive, motor, or perceptive skills; or due to substance abuse. Substance abuse has been described as a direct consequence of work stress and burnout for physicians.

**WELLNESS STRATEGIES**

Lack of wellness is a major problem for emergency clinicians and one that can have a huge impact on their personal lives, their families, the profession, and the health care system. Although there is a growing body of literature on the problem of burnout and compassion fatigue, the research surrounding how to address these problems is still in its infancy. What little literature does exist supports a multifaceted approach to the problem at the institutional, professional, and personal levels. The focus should be on preventing burnout and impairment, not just on identifying the impaired clinician and providing treatment.

Hospitals and other institutions could benefit from recognizing the impact of burnout and make wellness a priority. Studies have suggested that metrics for institutional success should include physician satisfaction and wellbeing. Too exist to assess physician wellness and satisfaction at a systems-level; instruments have also been developed that measure the overall health of an organization. The development of wellness committees, not just to deal with impaired physicians, but to monitor and respond to such metrics, have been successful at institutions, including Stanford University and the Permanente Medical Group of Kaiser Permanente. Many health care systems recognize that physician wellness is related to creating an efficient and fulfilling practice environment. Some have made "Physician Quality of Life" a regular agenda item at their medical executive, departmental, and board of trustee meetings.

Incorporation of mindfulness and teamwork training for physicians has also been recommended by some research. A study by West and colleagues found that a 9-month bi-weekly 1-hour facilitated discussion group incorporating elements of mindfulness, reflection, and shared experiences improved work meaning and engagement and reduced depersonalization even 12 months after the intervention. The physical health of physicians has also been the focus of some institutions. A study out of the Mayo Institute demonstrated that an incentivized exercise program increased physical activity and quality of life for residents and fellows who participated in the program versus those who did not. When more than 2000 physicians were asked how their institution could help with stress and burnout, the top requests included the following: more ancillary support to help with charting (eg, scribes); onsite exercise facilities or classes; wellness initiatives; and education on managing stress and burnout.

Institutions can also provide monitoring programs for at-risk physicians and should have resources to help impaired physicians. Physicians themselves are not especially good at detecting their own burnout or impairment. Employee assistance programs or wellness committees can serve this role. Referral to state
impaired-physician programs may also have a role in helping physicians salvage a career threatened by impairment or addiction. Programs to detect and treat physician impairment exist in every state of the United States.

**Professional**

Multiple studies have identified the fact that burnout and increased rates of depression begin early in the professional development of physicians, with rates of depression and burnout increasing as early as the third year of medical school.23-26 This has led to a call for early education in wellness and stress management for medical students and residents. A few medical schools have experimented with wellness programs, and some success has been observed with interventions such as self-development groups and the respiratory one method for relaxation.26

Wellness interventions in emergency medicine residency programs are less well-studied. The core content of emergency medicine includes wellbeing curriculum topics, including fatigue and impairment, time management/organizational skills, work/life balance, and work dysphoria (burnout). Some emergency medicine residency programs have developed wellness initiatives, including faculty mentors, big sibling programs, yearly retreats, self-reflection exercises, monitoring of wellness (eg, administration of the Maslach burnout scale and Jefferson Empathy Scale), mindfulness programs, compassion practices, and stress management programs.

As important as early education in wellness is, continuing education in wellness and stress management are equally important. Professional organizations should be at the vanguard of this mission. The American College of Emergency Physicians (ACEP) provides several lectures at their annual conference with regard to physician wellness and also provides wellness activities, including the Wellness Booth. ACEP has an online Wellness Handbook (updated in 2015) with every chapter devoted to different aspects of avoiding burnout and promoting wellness.

**Personal**

As important as institutional and professional responses to the wellness crisis in medicine are, the commitment to wellness ultimately is the responsibility of the individual physician. The majority of physicians enter the practice of medicine with an authentic desire to care for and heal fellow human beings. This initial altruistic desire can be eroded by the stress of training and the reality of the current health care environment. To adequately address the issue of wellness, physicians need to recognize that they are an important resource that needs nurturing and care.27

As with any procedural skill, physicians must look at the skills needed to remain emotionally and physically well. Self-care is essential and necessary for physicians to continue to show up and be present for the needs of their patients. At the very basis of self-care is the apparently obvious, but at times difficult to obtain, measures of getting enough sleep, obtaining adequate exercise, and adhering to a healthy diet. Time off that allows for reconnection with the aspects of life that are important to the individual is also essential.

A good personal practice is to self-monitor wellness on a regular basis. This can be done in many ways, including measuring one’s level of burnout, empathy, and level of satisfaction using established tools, such as the mini-Maslach, Jefferson empathy score, and/or the Adult APGAR score, all of which are available online. By tracking one’s responses on a regular basis, any drift toward burnout can be noted and serve as notice to pay more attention to self-care and wellness.

Frequently reassessing life priorities assures that one is making choices and living life in a manner aligned with what is personally important. Self-monitoring should occur on a regular basis (every 6 months to 12 months), as well as with any major life change (marriage, birth of a child, change of workplace, and so on). A sense of connection with a community, whether it is with colleagues, family, or friends is important, because isolation is a key component related to lack of wellness and burnout. Mindfulness and compassion practices can further enhance physicians’ resilience to burnout (Boxes e13.1 and e13.2).

Identifying specific and simple strategies to help emergency clinicians remain well is crucial to decreasing the frequency of burnout and compassion fatigue and, consequently, to the future of the specialty. Some of these tactics employed to maintain wellness include:

1. Be clear about what you want: Take time to write a personal mission statement. Too often a physician is not clear about priorities and what is important to him/her. There are many examples online of how to write a personal mission statement. Priorities may be educational, financial, oriented toward special interests or hobbies, family-oriented, or oriented to others. Writing down the list and putting them in order of importance will prevent the feelings of: “Where did all the time go? This is not what I really wanted.”

2. Join a group/find a practice where you are treated as a person, and feel appreciated. The best work environments are places that feel like both a family and a school—a family in the sense that people feel supported and surrounded by like-minded colleagues and a school in that people feel that they can continue to grow and expand their capabilities. Ensure that the group you join supports your strengths and helps you grow through your opportunities.

3. Make sure you create a renewal investment plan. Almost all physicians have a financial plan and an investment advisor,

---

**BOX e13.1**

**Example of a Mindfulness Meditation Practice**

**MINDFULNESS MEDITATION**

Find a comfortable seated position. Allow your spine to lengthen. If it is comfortable for you, close your eyes. Rest your hands on your knees or thighs. Take notice of your breath without attempting to change it. You might find it easiest to notice your breath as it comes in an out at your nostrils, or you may find it easier to be in touch with your breath as your belly rises and falls. Whatever technique works best for you, use your breath as an anchor to keep you present in the moment. It is natural that your mind will continue to have thoughts. When you notice yourself being carried away by your thoughts, just say to yourself, “thinking” without judgment and return to your breath.

Try this practice initially for 5 minutes, and try to increase it to 20 to 30 minutes a day.

---

**BOX e13.2**

**Example of Compassion Meditation Practice**

**COMPASSION PRACTICE**

Take a comfortable seat, and tune into your breath for several minutes. Once you feel grounded, begin by focusing on a beloved one. Picture them in your mind and say silently to them, “May you be happy, may you be healthy, may your life be easy,” or similar phrases that convey similar wishes to your beloved. Next send similar wishes to yourself, a neutral person in your life (eg, the grocery clerk, a person you pass on the street, and so on), someone who you have difficulty with in your life, and then to all sentient beings.
yet few have a formal renewal investment plan where they write down a specific action-oriented stepwise approach to remaining well.

4. Exercise regularly, eat right, and sleep more. Optimal exercise is 3 to 5 times a week for at least 45 minutes, and daily exercise does not have to be at one time (45 minutes can be split 15/15/15 depending on availability of time). No one diet is right for everyone, and breakfast is an important meal. If sleep is less than 6 hours a night, there is a 48% increase in the risk of heart disease and a 15% increase in the risk for stroke. Set an alarm for when it is time to go to bed, not just when to wake up.

5. Be more than just a shift worker. Physicians who contribute to their specialty, who become integral to the social fabric of their medical staff, and who attend their department meetings, develop a greater sense of control over their workplace and a greater sense of contribution to their community.

6. Help create your team. Ask colleagues and staff: “What can I do to help you have a great day in working with me?” Say thank you more. It takes three compliments to one criticism to create a positive work environment.

7. Take time away from the electronic interface. To truly let down, it is necessary to disconnect from electronic devices. This is important on days off and especially important on vacations.

8. Take more deep breaths. As mentioned previously, there are mindfulness techniques that can help physicians stay balanced even while in the chaotic highly stressed ED environment.

9. Stay connected to why you decided to do what you are doing, to others, to your spirit. Most physicians entered the profession to make a difference in people’s lives. This connection has to be remembered. The human connection is crucial to the healing process and to remaining well when giving care.

10. Practice gratitude. Every morning wake up and say thank you for something, even if it is just the opportunity to be present for another day. Consider keeping a gratitude journal where you write each day what you are most thankful for.

11. Spend time in nature every day (or as often as possible). Most EDs are boxes with no windows or exposure to the outside world. We need, as human beings to experience the sun, rain, and wind and to stay connected to the natural world around us.

12. Laugh every day. Laughter is truly great medicine. Spend time with people who make you happy or enjoy a movie, book, or Internet site that elicits laughter.

13. Hug and touch often. Human touch is paramount to health, wellness, and happiness. We live in a world and profession where the importance of touch has been minimized, and where there is even fear of touching due to concerns about it being inappropriate. Remember that human babies will die if they are not touched, so reach out to those who you are comfortable with (family, friends, your children, and so on) and share the power of physical connection.

KEY CONCEPTS

- Stress is a part of the human experience. The practice of emergency medicine, because of its unpredictable and chaotic nature, and because matters of life and death occur every shift, includes more stressors than most other professions.

- Emergency clinicians experience high rates of burnout and compassion fatigue, which threatens the future of the specialty.

- The approach to preventing burnout and promoting resilience must be multifaceted and involve institutional, professional, and personal strategies. Only by being specific and concrete in proactively creating a more supportive, efficient, and fulfilling work environment will health care institutions be successful in promoting physician wellness.

- At the departmental level, emergency medicine leaders should educate physicians, whether in practice, in residency, or in medical school, to cultivate resilience to meet the challenges that they will face.

- Emergency clinicians should take personal responsibility and develop the skills that they need to have long and satisfying careers in emergency medicine.
